Abstract. Ionograms from a standard vertical-incidence ionosonde chain (nine stations), obtained over a wide range of southern latitudes (in geom.lat. range: 23° – 52° S), were digitally scanned at 5-min intervals at nighttime (18:00–06:00 LT) for 13 months (January 2004–January 2005). An important parameter of the F-region, so-called range spread-F (Sr), was for the first time quantified in km. Maximum in Sr was recorded at a sounding frequency of 1.8 MHz for each night and for each ionosonde station. A distinct pattern in the magnitude (in km) and in the percentage occurrence of the range spread-F was present in southern winter only (the June solstice). The sub-auroral region (geom. lat. $\geq 52^{\circ}$ S) is characterised by consistently high spread-F (average $Sr \approx 100$ km) on 80–100 per cent of the observed nights. There is a sharp equatorward boundary in the spread-F activity in a latitudinal range: 52° – 48° S followed by a midlatitude region (44° – 48° S) which exhibits a peak in Sr (≈ 50 km) in winter only, observed on half of the nights. The midlatitude activity reaches its minimum at 42° – 43° S, with Sr less than 20 km on one third of the nights. The low mid-latitudes (23° – 36° S) are characterised by a strong peak in Sr again in winter, centred at about 30° S (average $Sr \approx 70$ km) on 80 per cent of the nights. The pattern becomes largely absent during other seasons particularly in southern summer (the December solstice) when spread-F activity shifts to sub-auroral latitudes. The pattern in the occurrence of spread-F appears to have a global character as the enhanced spread-F activity is observed in the Japanese sector in local summer (i.e. the June solstice).

It appears that the midlatitude spread-F minimum is only apparent but not real. It delineates the boundary between aurorally generated spread-F (due to travelling ionospheric disturbances, TIDs) and low midlatitude spread-F whose origin is not known.

Keywords. Ionosphere (Ionospheric disturbances; Ionospheric irregularities; Mid-latitude ionosphere)

1 Introduction

Early extensive studies of spread-F in southern midlatitudes (Brisbane) by Bowman (1960) indicate that ionosonde traces display different forms. One type observed at the low frequency end of ionograms is characterised by the occurrence of range spread-F (Sr) which show traces of 10 km or more over the true range of the main echo at a lower sounding frequency (< 2 MHz). At other times the low frequency spread can be small but the critical frequencies are spread, forming so-called frequency spread-F (Sf). Bowman (1960) concluded that range spread is associated with the frontal structure of irregularities with a linear extent of the order of 1000 km, due to the off vertical reflections of radio waves from the extended frontal irregularities. On the other hand frequency spread is due to the ionosonde echoes coming from the parts of the ionosphere close to the zenith. King (1970) suggested, from comparison of his own studies in New Zealand with those obtained in Australia, that Sr is more fundamental in studies of F-region irregularities than Sf. He concluded that range spreading consists of ridges in the F-region ionization and “the frequency spreading is simply the decay product of the range spreading”. Rastogi and Woodman (1978) reported from a study of vertical incidence ionograms, combined with the ionospheric scatter radar, that echoes due to range spread are much stronger than those associated with frequency spread. They suggested that: “range spread-F is caused by the existence of very strong and irregular vertical gradients of ionization at the base of the F-region including structure down to the 3 m scale length”. On the other hand frequency spread-F is due to a larger scale of irregularities, not conducive to the radar VHF scattering. Extensive study of ionospheric scintillations, from recordings of VHF transmissions from radio-satellites, indicates that range spread-F is the main cause of scintillations (Hajkowicz, 1977, 1978). Hajkowicz (1977) concluded that a difference in the spatial configuration of irregularities causing range and frequency spread leads to the preferential effect of range spread on generation of scintillations, following the model of spread-F given by Bowman (1960). The radio-scintillation

Table 1. Ionosonde stations used in this report in the Australian-New Zealand sector. Local midnight (LM) is shown in UT.

Station:	Geog. cord.		Geom. cord.	LM (UT)
	Lat. ° S	Long. ° E	Lat. ° S	
Hobart (H)	42.9	147.3	51.6	14
Christchurch (CC)	43.6	172.8	48.0	12
Canberra (C)	35.3	149.0	43.9	14
Mundaring (M)	32.0	116.3	43.4	16
Sydney (S)	33.9	150.6	42.2	14
Brisbane (B)	27.5	152.9	35.7	14
Norfolk Is. (N)	29.0	168.0	34.7	14
Townsville (T)	19.3	146.7	28.4	14
Darwin (D)	12.3	130.5	23.0	15

method tends to detect irregularities situated well away from the zenith hence scintillations would show better correlation with range spread than with frequency spread. Since the midlatitude scintillation model is still inadequate (due to shortage of midlatitude scintillation data) the new finding on spread-F morphology could be used as an important contribution to this field of ionospheric study.

Little is known about spread-F occurrence, from the real-time ionograms, at frequent time intervals and over a wide range of latitudes. Previous studies of this type were based on the hourly qualifying symbols (from the tables of ionospheric parameters), thus lacking the information on the magnitude of spread-F.

2 Method and results

The standard vertical-incidence ionograms from nine stations, obtained at 5-min intervals at night (18:00–06:00 LT),

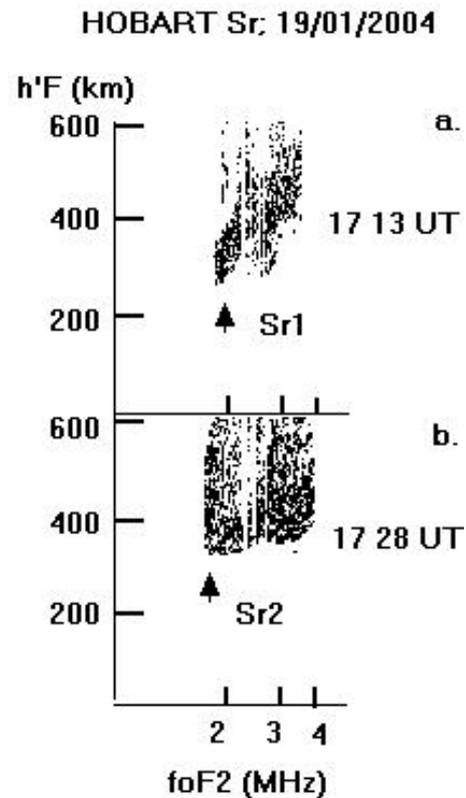

Fig. 2. Typical example of range spread-F intensified to a maximum at 17:28 UT (03:28 LT) at a low end of the ionosonde sounding frequency (1.8 MHz) at a sub-auroral station Hobart; here Sr1=100 km and Sr2=200 km.

were analysed for a period: January 2004–January 2005. The digital ionosonde stations were operated and uniformly calibrated by the Australian Ionospheric Prediction Service (IPS). Figure 1 shows the geographic locations of the ionosonde stations used in this study. The geographic and geomagnetic coordinates of the stations, as well as the time of local midnight in UT, are shown in Table 1 (stations symbols are given in the brackets). It can be seen that the latitudinal coverage of the ionosphere extended from high (Hobart, H) to low (Darwin, D) midlatitudes. The majority of the stations have local midnight at about 14 UT (LT=UT+10 h). The solid lines and broken lines refer to the latitudinal positions of maxima (MAX.1 and MAX.2) in spread-F activity whereas the dotted line (MIN.) refers to the latitudinal minimum in Sr.

Ionograms were digitally scanned for each station for consecutive nights at 5-min intervals and searched for a maximum in Sr. As an example Fig. 2 shows two typical ionograms obtained on the same night at the polewardmost station Hobart. The range spread-F increased from less than 100 km at 17:13 UT (03:13 LT) to a maximum of about 200 km 15 min later (b). Note that the evaluation of Sr at

higher sounding frequencies might be less accurate due to a steep rise in the virtual height ($h'F$) of the F-region.

Since this is the first numerical study of Sr it is important to define the reliability of this parameter. Unlike other tabulated ionospheric parameters (e.g. $h'F$, f_oF2) the calculation of Sr was based on the arbitrarily chosen sounding frequency being at the lower end of the frequency spectrum, unaffected by the frequency spread. On the whole this parameter was not affected by the blanketing frequency due to sporadic-E (fbEs). The uniform part of range spread-F, as shown in Fig. 2, was used to derive a specific value of Sr from the bottom to the top of the range spread. The striated traces of spread-F, as can be seen in Fig. 2a above the main trace, were filtered out. The nature of this type of analysis would allow accuracy of about ± 10 km. This is a considerable advancement over the study based on simple absence or presence of spread-F derived from the tabulated qualifying parameters (these parameters refer to the inability to define f_oF2 at the high end of the frequency scale due to the frequency spread-F). Clearly as this is the first attempt to introduce the index Sr a more rigorous approach would be required in the future to include this parameter in the tabulated ionospheric indices. A particular attention should be given to the uniformity of the trace at the low frequency range using a suitable algorithm.

It became evident from the ionogram analysis that during southern winter (the June solstice) that the midlatitude ionosphere can be divided to a region of consistently high Sr (sub-auroral lat., Fig. 3a) followed by decreasing Sr towards a mid-latitude minimum (Fig. 3b) and increasing again to a distinct maximum in lower midlatitudes (Fig. 3c). The first region, characteristic of a sub-auroral station Hobart, showed on the whole high average Sr during the year (a typical standard error is indicated as an example), with a shallow maximum ($Sr=125$ km) in May and a pronounced dip ($Sr=20$ km) in December. The auroral magnetic activity (average ΣK_p for each month) is also indicated. It can be seen that the nearest stations Christchurch (only 3.6° geom. equatorwards of H, cf. Table 1) and Canberra show a decreasing tendency in Sr, with the maxima in June–July.

Sr keeps on decreasing towards a minimum as recorded at Mundaring and Sydney where the winter maximum is barely discernable. The winter enhancement in Sr is clearly visible for the low midlatitude stations (B, N, T and D). Sr is the highest for Townsville and Brisbane (maximum in June–July reaching 70 km).

It can be seen that during other seasons, particularly during summer (the December solstice) there is little evidence of spread-F at all the stations except Hobart. It is of some interest that Christchurch, being the closest station to sub-auroral latitudes, exhibits a submaximum in January (Fig. 3b).

The seasonal trends in the percentage occurrences of Sr is summarised in Fig. 4. The broad autumn–winter shallow maximum (almost 100 per cent occurrence) at H is followed by more selective winter maxima at CC and C for which Sr

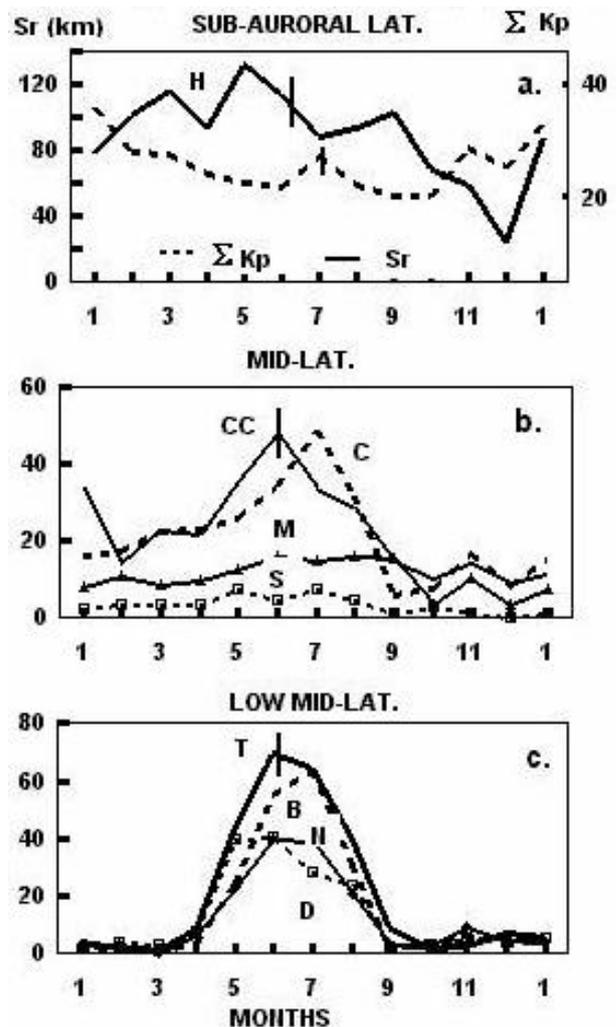

Fig. 3. Monthly (January 2004–January 2005) variations in the average magnitude of range spread-F in the different regions of the midlatitude ionosphere. A typical standard error (the vertical bar) is shown as an example.

was recorded only on the half of the nights (Fig. 4a). Note that there is a substantial spread-F activity also in autumn for Christchurch, the midlatitude station close to sub-auroral latitudes. The first station which shows a highly selective winter enhancement in Sr is Canberra (4.1° geom. equatorwards of Christchurch). The next midlatitude region exhibited only a weak winter maximum (Fig. 4b). The lowest percentage occurrence was for Sydney, below 20 per cent. The highly selective winter occurrence of Sr was in low midlatitudes (Fig. 4c). It can be seen that the percentage occurrence rate of Sr in winter for T and B peaks close to 80 per cent but falls dramatically during other seasons.

The summary of Sr (i.e. the average value for each season and each station) variations vs. geom. lat. is shown in Fig. 5. It can be seen that there is a sharp poleward increase in Sr (by a factor of 2) towards sub-auroral latitudes, particularly in

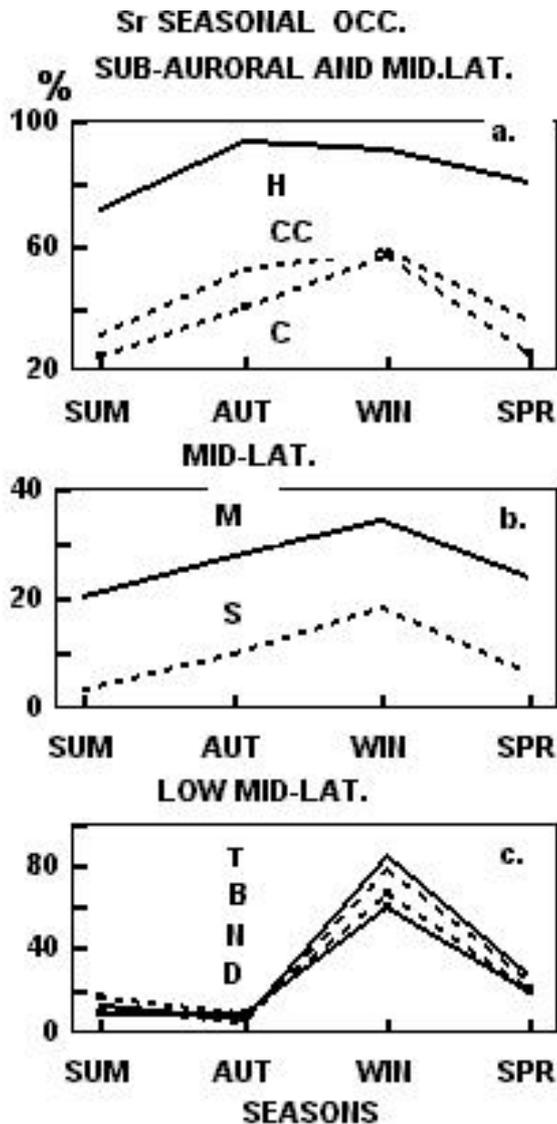

Fig. 4. Seasonal percentage occurrences of range spread-F at the different ionospheric regions and for different stations.

autumn and winter. The midlatitude minimum (for Mundaring and Sydney) is consistently observed throughout the year. A pronounced lower midlatitude maximum is observed in winter only. The values of Sr for Brisbane and Norfolk Is. are very similar as these stations are separated by one degree in latitude.

3 Results and conclusions

Ionograms obtained at 5-min intervals for 9 Australian and New Zealand stations (in geom. lat. range: 23° S–52° S) were analysed for a period of over one year (January 2004–January 2005). For the first time a quantitative magnitude (in km) was assigned to the range spread-F (Sr) at a specific ionosonde

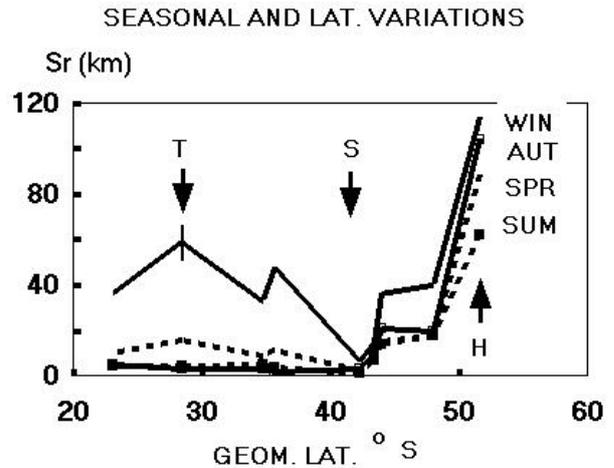

Fig. 5. Latitudinal cross-sections of the mean range spread-F at different seasons. The geomagnetic positions of the stations for which maxima (Townsville-T and Hobart-H) and a minimum (Sydney-S) were observed are shown by the arrows. A typical example of the standard error is indicated.

sounding frequency (1.8 MHz). The previous statistical studies of spread-F were usually based on a qualitative approach (e.g. using qualifying symbols referring to the absence or presence of spread-F at the higher sounding frequencies).

It was found that the sub-auroral ionosphere is characterised by ionograms obtained at the southernmost station Hobart. This region is associated with strong and frequent Sr, occurring on about 90 per cent of nights. Average Sr is about 100 km. There is a sharp decrease in the occurrence and magnitude of the range spread equatorwards of Hobart (51.6° S) towards Christchurch (48.0° S) and Canberra (43.9° S), with a consistent minimum observed at Mundaring (43.4° S) and Sydney (42.2° S). There is negligible spread-F at lower latitude stations at all seasons except in winter when it strongly peaks at Brisbane (35.7° S) and Townsville (28.4° S). Thus latitudes of two spread-F maxima and a distinct minimum can be defined as shown in Fig. 1: sub-auroral ionosphere associated with consistently pronounced spread-F (MAX.1), a narrow region of consistently weak spread-F activity (MIN.) and finally the low midlatitudes in which Sr has a distinct peak in winter (MAX.2). The region of diminished spread-F activity (MIN.) is a relatively new feature in the spread-F morphology. Rawer and Suchy (1967) found a similar distribution of midlatitude spread-F on the global scale. They found a boundary between low and high midlatitude spread-F occurrence.

It is of considerable interest that the June solstice maximum in spread-F activity is also present in the Japanese sector in the Northern Hemisphere during local summer. An extensive study of this phenomenon, over a solar cycle, clearly indicates that both the Australian sector (Canberra, Brisbane, Townsville) and the Japanese sector (Wakkanai, Akita,

Yamagawa) are characterised by a distinct solstice maximum in this parameter (Bowman, 1964). He associated some of the reported effects with the upper atmosphere neutral particle density (NPD) variations. In particular the June solstice maximum in the global spread-F seems to be inversely correlated with NPD which is then at minimum. A similar increase in the June solstitial spread-F in East Asia (Japan and Taiwan) was reported by Sinno and Kan (1980), and Huang (1978). The June solstice maximum in spread-F was also reported for the South African longitudinal sector (Lambert, 1988).

Bowman (1992) found that “midlatitude spread-F is caused primarily by off-vertical reflections of radio waves from tilted isoionic surfaces produced by the passage of medium-scale travelling ionospheric disturbances (MS-TIDs)”. The global trend in NPD is such that it is small during the June solstice which provides favourable condition (due to a smaller attenuation) for the propagation of MS-TIDs leading to the enhanced spread-F activity in both hemispheres. This is further supported by the global minimum in midlatitude spread-F during the solar cycle maximum. The increased frequency and intensity of auroral disturbances during sunspot maximum is also associated with an increase in the global NPD which results in greater attenuation of MS-TIDs hence leading to the well known spread-F minimum (Bowman, 1964, 1993). This theory can be applied to the latitudinal range between sub-auroral and mid latitude stations (i.e. between 43–48° S). However the low midlatitude winter maximum (following the deep minimum) indicate a different mechanism in generation of spread-F, incompatible with the NPD model. Clearly, the generation of midlatitude spread-F is a complex phenomenon which has no satisfactory explanation. It is suggested that aurorally generated TIDs are not the primary cause of spread-F in low midlatitudes. The midlatitude minimum delineates a boundary where the effect of aurorally generated TIDs could cause spread-F. In this sense the minimum is only apparent but not real. The following maximum is due to an entirely different phenomenon hitherto unknown.

Although it has been known for some time that the occurrence of spread-F is larger at Hobart than at lower southern latitudes stations (cf. Bowman, 1960) the limited availability of ionosonde stations made it difficult to define a transition region between higher and lower midlatitudes. The transition region between these regions can be however inferred from other ionospheric studies. In particular the well known close association between Sr and VHF ionospheric scintillations may be applicable (e.g. Hajkowicz, 1977, 1982a, 1994). Kersley et al. (1975) using VHF radio transmissions from orbiting satellites concluded that a rapid scintillation increase from mid-latitudes to sub-auroral latitudes occurred over 3° of invariant latitude. Similar results were obtained in New Zealand where a scintillation boundary (using the same technique) was found at geomagnetic latitudes 50°–55° S (Kaiser and Preddey, 1968). The boundary was aligned along the ge-

omagnetic latitude and was associated with a sharp scintillation increase from midlatitudes to sub-auroral latitudes. Preddey (1969) conducted scintillation observations in the same region using a chain of latitudinally displaced stations and found a weak maximum at 35° S invar. lat., minimum at 45° S and a strong scintillation increase towards higher latitudes. Hajkowicz (1982b) noted that the equatorwards position of auroral scintillation boundary, associated with the simultaneous occurrence of range spread-F, extended at least to the latitude of Hobart during geomagnetically disturbed periods.

These results indicate the presence of a well defined small-scale irregularity boundary, deduced from VHF scintillation (caused by kilometeric irregularities) and range spread-F studies. The winter low midlatitude maximum in Sr can be linked with the winter maximum in ionospheric scintillations found from two-year study by Hajkowicz (1977). Hajkowicz (1994, 1997) found, from a long-term study, that a specific type of midlatitude scintillations and range spread-F both reach maximum during sunspot minimum.

The fast decline in the range spread between Hobart and Christchurch can be linked with the structure of irregularities linked with this phenomenon. Bowman (1981, 2001) concluded that the nighttime irregularities which produce spread-F have quasi-sinusoidal cross sections at F-region heights, with a wavelength of several tens of kilometres. This type of wave-like structure is associated with travelling ionospheric disturbances (TIDs) which are frequently generated in the auroral zone as a result of substorm activity. It became evident, from a study of the spectrum of TIDs generated during auroral substorm activity, that waves (with wavelengths below about 30 km) were rapidly attenuated during their equatorward propagation (Williams et al., 1988). It follows that the small latitudinal separation between Hobart and Christchurch is sufficient to produce a substantial decline in spread-F activity. This decline continues towards the midlatitude region where a minimum is observed.

The correlation between auroral activity and spread-F occurrence is a complex phenomenon, outside the scope of the present paper. Bowman (1982) conducted an extensive study on the occurrence of spread-F following the magnetic storms. He noted a substantial delays (days) between auroral substorms onsets and the resulting midlatitude spread-F. It can be seen from comparison of sub-auroral Sr with mean ΣK_p (Fig. 3a) that there is little evidence on day-to-day correlation between Sr and substorm activity.

There is possible link between simultaneous occurrences of mid-latitude spread-F and sporadic-E. Haldoupis et al. (2003) noted that mesoscale midlatitude spread-F is closely linked with patchy sporadic-E layers due to gravity wave-induced large-scale electric fields mapping the E region to the F-region. This is however may be less common since the southern winter maximum in Sr coincides with the seasonal minimum in sporadic-E (Hajkowicz, 1977, 1978).

The existence of a distinct minimum in the midlatitude spread-F is a relatively new aspect in this study hitherto reported only by Rawer and Suchy (1967) and indirectly from the results obtained by Preddey (1969) from a scintillation study. It creates a clear midlatitude ionospheric boundary between sub-auroral and low midlatitudes.

The study of midlatitude ionosphere is gaining popularity in recent years. Kelley and Miller (1997) pointed out to “a growing awareness of the interconnections between gravity waves, travelling ionospheric disturbances, elongated bands of raised ionosphere density depletions, and the recently discovered turbulent upwelling of midlatitude plasma”. The Perkins instability has been widely used to explain midlatitude spread-F. Huang et al. (1994) suggested that seeding by atmospheric gravity waves is an important factor in the generation of midlatitude spread-F irregularities. They expanded the Perkins linear instability which become significantly enhanced due to gravity waves seeding of midlatitude ionosphere.
