**Abstract.** We investigate particle and fields data during a conjunction of the Polar and Cluster spacecraft. This conjunction occurs near the dayside cusp boundary layer when a dayside inverted-V was observed in the particle data of both satellites. Electron, ion, electric field, and magnetic field data from each satellite confirm that the dayside inverted-V (DSIV) structure is present at the location of both satellites and the electric fields persist from the altitude of the Polar (lower) spacecraft to the altitude of the Cluster spacecraft. We observe accelerated, precipitating electrons and upward ions along the magnetic field. In addition, large amplitude electric fields perpendicular to the ambient magnetic field seen by Polar and by Cluster suggest significant parallel electric fields associated with these events. For similar DSIV events observed by the Polar spacecraft, plasma waves (identified as possible Alfvén waves) have been observed to propagate in both directions along the magnetic field line. Future conjunctions will be necessary to confirm that DSIVs are associated with reconnection sites.

**Keywords.** Magnetospheric physics (Auroral phenomena; Energetic particles, precipitating; Magnetopause, cusp, arid boundary layers)

## 1 Introduction and background

The term “Inverted-V” is used to describe the signature of auroral electron precipitation as observed on energy-vs-time spectrograms seen on both the nightside and dayside of the Earth. In the satellite frame, intense electron flux is first seen to increase to a maximum and then decrease forming the characteristic inverted-V on an energy-time spectrogram of particle flux. On the dayside Lin and Hoffman (1982)

long ago reported the occurrence rates of inverted-Vs in a statistical study using the Atmospheric Explorer-D data. They found that the likelihood of observing inverted-Vs is a maximum in the region between about 10 h < MLT < 12 h and invariant latitude < 80°. We refer to inverted-Vs in this region as dayside inverted-Vs, (DSIVs). Lin and Hoffman also reported that DSIVs are shorter in spatial extent than those in the evening sector and DSIVs have a peak energy of only about 1 keV compared to about 5 keV for the evening hours from 19:00 to 01:00 MLT.

Following that early study, Burch et al. (1990) conducted a study of currents associated with DSIVs in the morning sector of the Earth. These authors found DSIVs typically exhibit acceleration potentials about ten times smaller than acceleration potentials exhibited by DSIVs found on the Earth’s nightside. Burch et al. found that the DSIVs are not permanent features of the dayside auroral region, but typically occur just equatorward of the cusp or cleft in a region which contains trapped electrons and is believed to map to the boundary layer, i.e., on closed field lines just equatorward of the cusp. Downward region-1 currents are observed either just poleward of the trapping boundary in the equatorward part of the cusp or sometimes within the same flux tubes as the inverted-V events. Lin and Winske (1987) and Lin et al. (1986) have defined the region consisting of mixed plasma from both the cusp and the dayside auroral region as the cusp boundary layer. In the reconnection model (cf. the review by Vasyliunas, 1975), interplanetary magnetic field lines at a dayside neutral point, or multiple points reconnect to terrestrial magnetic field lines in the current layer of the magnetopause, force the merging plasma to flow or accelerate into the boundary layer. In this model, the boundary layer is a region of partially open and closed magnetic field lines which convects anti-sunward for southward IMF conditions. Magnetosheath plasma is observed in the boundary layer. After merging with solar wind field lines, cusp magnetic field lines

(jdm@space.physics.uiowa.edu)

initially have a significant east/west motion due to field line tension. This motion eventually becomes antisunward due to drag by the magnetosheath flow (Saunders, 1989).

Menietti and Smith (1993) presented several examples of dayside inverted-Vs in which ion convection and energy dispersion appeared to span the region of both open and closed field lines. All of their examples occurred for negative  $B_z$  within the region generally called the low latitude boundary layer, or the cusp boundary layer, and suggest a connection between closed field lines of the dayside auroral region and open field lines of the dayside cusp. One explanation is that plasma in the cusp boundary layer on closed field lines convects across field lines (in unusually smooth fashion) into the cusp. Such cross-field line convection may be possible in regions of finite conductivity and strong currents, where the field can diffuse through the plasma. Another explanation is the mid-altitude manifestation of merging at the dayside magnetopause causing the opening of previously closed field lines.

It is widely known that for conditions of negative  $B_z$  magnetic reconnection plays an important role in the dynamics of the solar wind magnetosphere-ionosphere coupling process (cf. Onsager and Fuselier, 1994; Scudder et al., 2002). There is also clear evidence for reconnection during northward IMF. Burch et al. (1980) reported “reverse-dispersion” of ions occurring during these purported cases at high latitude, poleward of the cusp. Onsager and Fuselier (1994) report evidence of reconnection for northward IMF equatorward of the cusp. Reconnection for northward IMF takes place at higher magnetic latitudes (Reiff, 1984; Song and Russell, 1992; Russell et al., 2000) with a consequent formation of a low latitude boundary layer on closed field lines (cf. Le and Russell, 1996; Lockwood and Moen, 1999).

Transient reconnection may account for the particle population throughout the cusp (Smith and Lockwood, 1990; Onsager et al., 1993). In this scenario, reconnection is initiated at the dayside magnetopause. The reconnection potential along the X-line will excite flows in the ionosphere. Initially a flow in the east-west direction, dependent on the sign of  $B_y$ , will occur due to field line tension. Later the solar wind flow will pick up the field line and drive it antisunward. Cowley et al. (1991) and Smith et al. (1992) discuss, in addition, an inductive effect which will move the merging line equatorward in the ionosphere, thus causing formerly closed field lines to become open.

The DSIV carries an upward current from the ionosphere (Burch et al., 1990) and may be a result of the reconnection process, but the plasma of the field lines still appears closed at the time and location of the observations by DE-1, because the high-energy trapped plasma had not enough time to escape along the now open field lines. The region-1 currents carried by the upward electrons observed just poleward of the DSIV and equatorward of the cusp may be due to current closure through the ionosphere (cf. Southwood, 1987; Saunders, 1989; Smith and Lockwood, 1990). It should be

noted that DSIVs are not observed on every satellite pass. The cusp or cusp boundary layer is often observed without the presence of a DSIV (cf. Burch et al., 1990). The source mechanism generating the DSIVs is thus transient.

The dayside inverted-V may signify a potential on a re-connecting field line, with the maximum energy signifying the instantaneous position of the reconnection line. The drop in high energy electrons poleward of the reconnection line signifies newly opened field lines. Thus the cusp boundary layer may be a transitional region with field lines that have just opened and still containing some magnetospheric plasma. As the region is opened it moves under tension. For  $-B_y$ , the flux tube would move eastwards according to the model of Southwood (1987) and Saunders (1989). As the magnetopause end moves it will communicate this to the ionosphere by stresses in the field line, i.e., field-aligned currents. For the ionospheric footprint to move in the correct direction there must be a downward current on the poleward side and an upward current on the equatorward side. The poleward current can only be obtained from low-energy ionospheric electrons. These electrons will collapse in pitch angle with altitude and be seen as beams as observed in the DE-1, Polar, and Cluster data.

### 1.1 Alfvén waves

Goertz (1984) has discussed magnetosphere-ionosphere coupling due to Alfvén waves on auroral field lines. In some reconnection scenarios, Alfvén waves are believed to be present along magnetic field lines that connect to a reconnection site. Using Dynamics Explorer particle and wave data, Gurnett et al. (1984) have discussed the efforts at observing Alfvén waves on nightside auroral field lines. Louarn et al. (1994), using FREJA data, have reported the existence of these waves for nightside aurora. More recently, Wygant et al. (2000) and Keiling et al. (2003a, b) have identified significant Poynting flux associated with intense Alfvén waves observed in the nightside aurora by the Polar electric field instrument.

In the low latitude boundary layer (LLBL) and magnetopause there have also been observations of Alfvén waves. These are summarized in review papers by LaBelle and Treumann (1988) and by Tsurutani et al. (2003). These waves are not as intense as those observed in the nightside auroral zone, and detailed analysis of these waves and the role they play in dayside reconnection needs further study.

Satellite observations have shown that field aligned currents (FACs) are carried by Alfvén waves along flux transfer events (FTEs) (Saunders et al., 1984). FTEs are considered time-dependent observations of reconnection at the dayside magnetopause (Russell and Elphic, 1978). Lee et al. (1988) have presented a mechanism by which the Alfvén waves carrying FACs propagate away from the magnetopause to the ionosphere. Ma and Lee (1999) have used MHD simulation studies of the dayside reconnection region with and without

an initial guide magnetic field ( $B_y$ ). These authors have clearly demonstrated how Alfvén waves propagate from the reconnection site downward toward the ionosphere and toward the sun. Alfvén waves on closed magnetic field lines will reflect near the ionosphere to generate standing waves. This effect has been verified by ground observations (e.g., Lanzerotti et al., 1986).

Recently, Mozer et al. (2004, 2005) have reported observations of large, impulsive electrostatic fields predominately perpendicular to the magnetic field. These fields are observed on the magnetospheric side of the magnetopause and have magnitudes up to 140 mV/m. They are observed within local minima of plasma density. Jovanovic et al. (2006) have argued that these impulsive signals are oblique cylindrical electron holes that can be related to the nonlinear evolution of the Buneman instability of lower-hybrid waves, driven by the parallel electric field that is generated by collisionless reconnection. Lower hybrid waves are commonly observed along the magnetopause (cf. Andre et al., 2001; Bale et al., 2002; Menietti et al., 2004).

In this paper we investigate a DSIV observed by the Polar spacecraft during a higher altitude conjunction with the Cluster spacecraft. We analyze the particle and fields data from these spacecraft in an effort to determine the morphology and source of DSIV structures and their possible association with dayside reconnection.

## 2 POLAR instrumentation

The Polar spacecraft orbit provides an excellent opportunity to study the dayside magnetopause and cusp region. The plasma wave instrument on board this satellite obtained data from about 25 March 1996 to 16 September 1997. We have conducted an incomplete survey that identifies over 500 passes within the region of interest (e.g., where the maximum of the DSIVs occur). Polar is the first satellite to have 3 orthogonal electric antennas ( $E_u$ ,  $E_v$ , and  $E_z$ ), 3 triaxial magnetic search coils, and a magnetic loop antenna, as well as an advanced plasma wave instrument (Gurnett et al., 1995).

### 2.1 PWI

The Plasma Wave Instrument (PWI) on the POLAR spacecraft is designed to provide measurements of plasma waves in the Earth's polar regions over the frequency range from 0.1 Hz to 800 kHz. Five receiver systems are used to process the data: a wideband receiver, a high-frequency waveform receiver (HFWR), a low-frequency waveform receiver (LWFR), two multichannel analyzers, and a pair of sweep frequency receivers (SFR). Details of each of these receivers may be found in Gurnett et al. (1995).

### 2.2 HYDRA

The Electron and Ion Hot Plasma Instrument (HYDRA) (Scudder et al., 1995) is an experimental three-dimensional hot plasma instrument for the POLAR spacecraft. It consists of a suite of particle analyzers that sample the velocity space of electrons and ions between  $\sim 2$  keV/q to 35 keV/q in three dimensions. The time resolution for a complete 3-D phase space distribution is about 6 s. The instrument has been designed specifically to study accelerated plasmas such as those existing in the cusp and auroral regions.

### 2.3 EFI

The Electric Field Instrument (EFI) on the Polar spacecraft (Harvey et al., 1995) measures the three components of the ambient vector electric field and the thermal electron density. Spherical probes are used to obtain potential differences between opposite sphere pairs mounted along booms in order to measure the three components of the electric field over the frequency range from DC to  $>20$  kHz. The dynamic range is from 0.02 to 1 V/m. By measuring the floating point potential of the spacecraft, the plasma density may be obtained from about 0.01 to over  $10 \text{ cm}^{-3}$ .

### 2.4 MFI

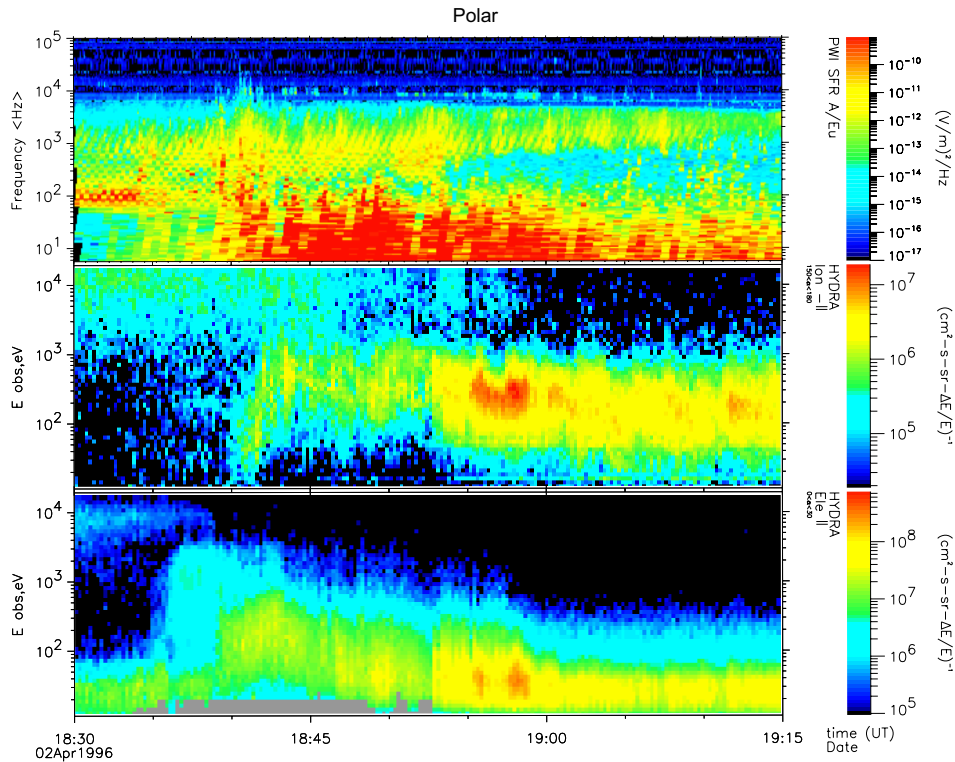

The Polar Magnetic Fields Investigation (MFI) (Russell et al., 1995) is a high precision instrument that measures magnetic fields in the magnetosphere using three ranges: 700, 5700, and 47 000 nT. The instrument consists of two triads of orthogonal fluxgate magnetometer sensors mounted on a 6 m boom. The data are now available at a sampling rate of about 54 vectors/s.

## 3 CLUSTER instrumentation

The Cluster II mission consists of four identical satellites in a high-inclination orbit with a nominal apogee of  $19.5 R_E$  and perigee of  $4 R_E$ . The mission objectives include studies of the magnetopause and magnetotail reconnection sites of magnetospheric phenomena.

### 3.1 PEACE

The PEACE (Plasma Electron and Current Experiment) is designed to measure the electron distribution function in the energy range from 0.6 eV to  $\sim 26$  keV (Johnstone et al., 1997). PEACE has many operational and telemetry modes. For this study, (gyrotropic) pitch angle distributions (PAD) generated from spectra containing the magnetic field during each spacecraft spin ( $\sim 4$  s) were used. The Low Energy Electron Analyzer (LEEA – 0.6 eV to 1 keV) and the High Energy Electron Analyzer (HEEA – 35 eV to 26 keV)

**Fig. 1.** Spectrograms of the Polar HYDRA electron and ion energy flux and the PWI electric field spectral density for a pass of the Polar spacecraft on 2 April 1996. The top panel is the PWI data from the SFR which shows the typical signatures of cusp whistler mode hiss. The second panel is upward ion flux density and the bottom panel is Earthward electron flux density. Seen in this figure is the cusp signature of low energy, high density plasma that begins at about 18:52:30 UT and continues poleward.

are used to sample subsets of their energy range (93 logarithmically spaced steps), which at times, overlap.

### 3.2 CIS

The Cluster Ion Spectrometer (CIS) experiment (Réme et al., 1997) provides 3-D simultaneous ion distribution functions in the energy/charge range from 5 eV/e to  $\sim 40$  keV/e for the major ion species ( $H^+$ ,  $He^+$ ,  $He^{++}$ , and  $O^+$ ) with a time resolution of  $\sim 4$  s (the satellite spin period). Two different instruments are used to cover the entire energy range. The CIS-2 instrument (a top-hat quadri-spherical analyzer) selects ions according to their energy per charge in the range from 5 eV/e to 32 keV/e. The CIS-1 instrument is the time-of-flight ion composition and distribution function analyzer, and the high resolution mass-resolving spectrometer operating in the energy/charge range from  $\sim 20$  eV/e to  $\sim 40$  keV/e.

### 3.3 EFW

The Electric Field and Wave (EFW) instrument on Cluster (Andre et al., 2001) consists of 4 spherical probes, 8 cm in diameter, at the end of long wire booms in the spin plane. There are many modes of operation available associated with 4 output data rates and 5 low and high band pass filters. In

normal mode, two electric field components in the spin plane are low-pass filtered at 10 Hz and sampled at 25 samples/s. In the burst mode the data rates of 22 240 and 29 440 bits/s may be used to transfer 3 or 4 signals sampled at 450 samples/s.

## 4 Observations

Dayside inverted-Vs are observed by the Polar spacecraft not infrequently. By the time the Cluster science mission began in 2001, the plasma wave instrument on board the Polar spacecraft was no longer in operation. Hence, there are no plasma wave data available from the Polar spacecraft during the Polar-Cluster conjunction period. However, it is instructive to analyze a typical example of a DSIV during the time when the PWI was operating on the Polar spacecraft.

In Fig. 1 we show a spectrogram of the HYDRA electron and ion energy flux and the PWI electric field spectral density for a pass of the Polar spacecraft on 2 April 1996. The top panel shows the PWI data from the SFR. Common signatures of cusp whistler mode hiss near 1 kHz and above are observed. The second panel shows the upward ion flux density and the bottom panel shows the Earthward electron flux density. These panels display the typical cusp signature of low-energy, high-density plasma that begins at about

**Fig. 2a.** The waveform from the PWI LFWR on board the Polar spacecraft. This figure shows the 3 electric and 3 magnetic field measurements in field-aligned coordinates, and extends over a time interval of about 2.56 s. The fields have been filtered for frequencies below about 8 Hz. The proton cyclotron frequency at this time is about 7.7 Hz. Note the rather large electric fields reflected in the first two panels where the electric field is perpendicular to the ambient magnetic field, which we believe are signatures of an Alfvén wave.

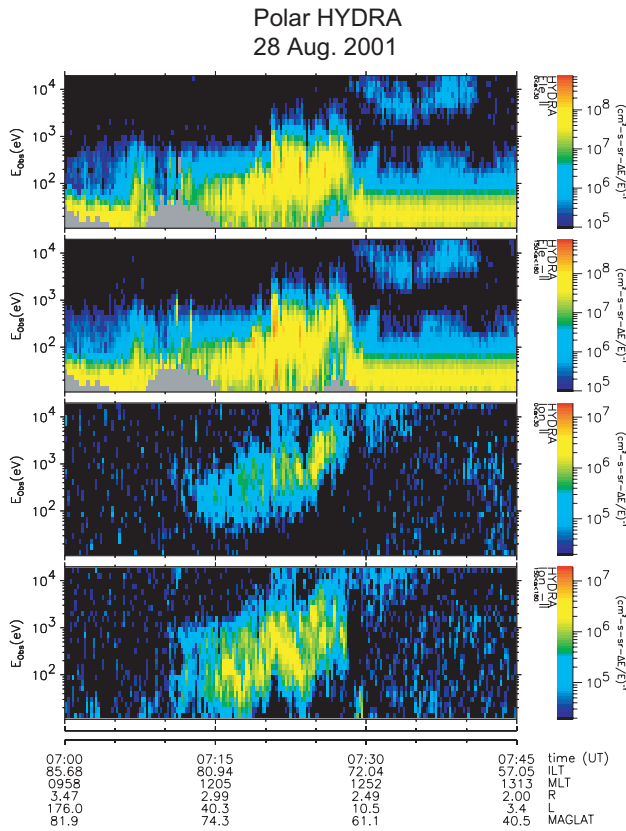

**Fig. 2b.** A higher resolution plot of perpendicular electric and magnetic fields (first four panels) shown in Fig. 2a during the Alfvén wave. In the bottom panel we plot the index of refraction.

18:52:30 UT. The cusp boundary layer exists just equatorward of the cusp in the time interval from about 18:39 UT to 18:52:30 UT. Within the cusp boundary layer, an inverted-V (DSIV) is visible. This signature is characterized by an inverted-V structure in the energy distribution centered near 18:43 UT as observed in the electron energy flux for energies less than 300 eV and in the upward accelerated ions, distinctive evidence that there exists a field-aligned electric field both above and below the spacecraft.

In Fig. 2a we show a plot of the waveform taken from the PWI LFWR on board the Polar spacecraft. This figure shows the 3 electric and 3 magnetic field measurements in field-aligned coordinates, and extends over a time interval of about 2.56 s. Oscillations in the fields have been filtered for frequencies below about 8 Hz. The proton cyclotron frequency at this time is about 7.7 Hz. Note the rather large electric fields in the first two panels where the electric field is perpendicular to the ambient magnetic field. These mag-

nitudes are about an order of magnitude smaller than those sometimes seen in the nightside auroral region, but they are nevertheless significant and are probably due to an Alfvén wave. For the time range covered in this figure, we have determined that the Poynting flux is propagating down the magnetic field line toward the Earth. At other times during this same satellite pass, we observe the Poynting flux is directed away from the Earth with about the same magnitude. This could be an example of a standing Alfvén wave along the reconnecting magnetic field line.

We have investigated the measured ratio of  $cB/E$  from the data of Fig. 2a. During the interval of peak electric fields observed just after 18:43:05.724 UT, this ratio varies from about 20 to 65, with a median of about 44 (see Fig. 2b). We can compare this to the expected index of refraction for an Alfvén wave using the local plasma parameters. At this time we observe  $f_{ci}=7.48$  Hz, so we can estimate the Alfvén velocity to be  $\sim .049c$ , or  $n_A=20.4$ . This is within a factor of 2 of the measured index of refraction, thus consistent with our interpretation of an Alfvén wave. We note that the presence of an Alfvén wave does not preclude the presence of static field-aligned potentials within the dayside and nightside auroral regions. The occurrence of such potentials are known

**Fig. 3.** Spectrogram of the Polar HYDRA electron and ion energy flux for the DSIV event of 28 August 2001. Beginning at the top, the panels shown are downward and upward electrons, and downward and upward ions. Inverted-V structures are observed in the interval from about 07:20 UT to 07:30 UT.

to exist in the auroral region even though Alfvén waves have been observed as probable accelerators of electrons as well (cf. Ergun et al., 1998; Wright, 2005; Wygant et al., 2000).

#### 4.1 Conjunction pass of 28 August 2001

In Fig. 3 we present observations from 28 August 2001, when Polar and Cluster spacecraft were in near conjunction in the Northern Hemisphere during a DSIV observed by the Polar spacecraft. At this time, the interplanetary magnetic field (IMF) is in the range  $-4 \text{ nT} < B_z < -2 \text{ nT}$ . During this observation, the Polar spacecraft is moving away from the northern pole, while the Cluster spacecraft travel toward the pole. The Cluster C1, C2, and C4 spacecraft (C3 is not included in this study because there was no PEACE telemetry at this time) are separated by  $\sim 1000 \text{ km}$  in Geocentric Solar Ecliptic (GSE) X, but are quite close in both GSE Z and Y. The order of trajectory is C4 first, then C2 followed by C1.

The Polar spacecraft observed the beginning of DSIV plasma at approximately 07:24 UT. At 07:26:45 UT, the Polar spacecraft detected the center of the inverted-V at invari-

**Fig. 4.** The magnetometer data obtained by the MFE on board the Polar spacecraft for the same time interval. The figure shows  $\text{dB}_x$  and  $\text{dB}_y$  (perpendicular to ambient magnetic field) in field-aligned coordinates. The characteristic signature of a field-aligned current is observed along with  $f \sim 1/30 \text{ s}$  fluctuations.

ant latitude,  $IL=74.4^\circ$ ,  $r=2.6 R_E$ , and magnetic local time,  $MLT=12.99 \text{ h}$ . By about 07:29 UT the Polar spacecraft has passed through the DSIV and is observed to enter the region of trapped particle fluxes, characterized by higher energy electrons and ions. During the inverted-V, the HYDRA observes downward energy fluxes with  $E_{\text{max}} \sim 2 \text{ keV}$ . Near 07:21 UT, HYDRA observes a narrow region of upward electron flux and downward ion flux. This peak upward energy flux also has an  $E_{\text{max}} \sim 2 \text{ keV}$ .

In Fig. 4 we plot the magnetometer data obtained by MFE on board the Polar spacecraft for the same time interval. In this figure, the two panels display  $\text{dB}_x$  and  $\text{dB}_y$  (perpendicular to  $B_0$ ) in field-aligned coordinates. The characteristic signature of a field-aligned current (FAC) is indicated by reference to the E-field data provided by the Polar EFI and displayed in Fig. 5a. Clearly, significant  $E_\perp$  fields are present in the interval 07:18–07:29 UT, indicating a strong  $E_\parallel$  below the spacecraft. For a model current slab assuming maximum  $B_y$  to be parallel to the current wall, we estimate that an upward current (downward electrons) of  $J \sim -0.27 \mu\text{amps/m}^2$  is present at this time. In Fig. 5b we plot, over the shorter time interval 07:18 to 07:30,  $\int \mathbf{E} \cdot d\mathbf{L}$  versus time where  $\mathbf{E}$  is the electric field and  $d\mathbf{L}$  is along the spacecraft velocity. There are a number of reversals of the electric field—a large one beginning after 07:20:30 indicating a significant change of electric potential from  $-25 \text{ kV}$  to  $-15 \text{ kV}$ . This time corresponds to the significant field-aligned electrons and ions observed at the same time on

**Fig. 5a.** The presence of a field-aligned current (FAC) is indicated by this electric field data provided by the Polar EFI. In this figure the 3 panels display the x, y, and z components of E with z parallel to B.

Fig. 3. A smaller reversal begins near 07:23:30, and one of intermediate size begins near 07:26:45. This latter reversal extends from about  $-47.8$  kV to  $-44.6$  kV within the inverted-V structure identified previously.

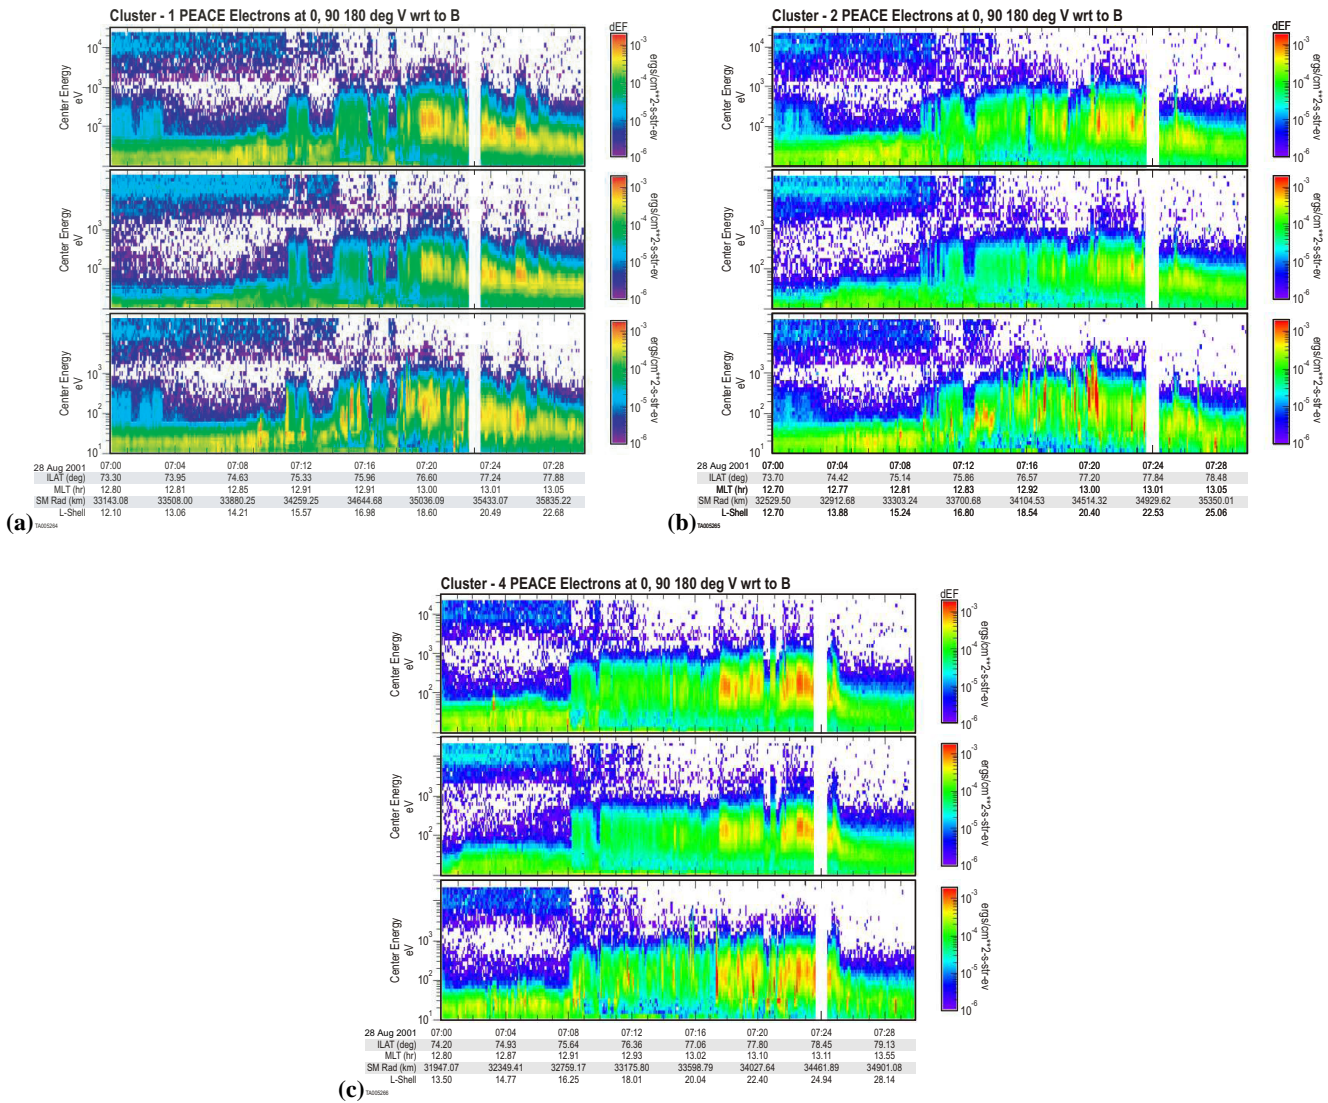

Cluster PEACE data for electrons are displayed in Figs. 6a–c for the approximate time interval 07:00 UT–07:30 UT. The format for the panels (top to bottom) is energy flux for downward, trapped ( $90^\circ$  pitch angle), and upward electrons. In Fig. 6a we observe the C1 satellite exiting the dayside auroral region and entering the cusp boundary layer in the time interval 07:14 UT to about 07:18 UT. Rather intense downward electrons (top panel) begin at about 07:19:30 UT, but a most distinctive feature of the C1 fluxes is the spiky upward electrons that are present throughout the cusp boundary layer. Both downward and upward electron fluxes show  $E_{\max} \sim 900$  eV. The electron fluxes on C4 are similar to those of C1, and show a dominant downward electron flux beginning about 07:17:30 UT. Electron fluxes observed by C2 are most dominant in the downward direction, but intense upward electron fluxes near 07:20 UT with a maximum energy of  $E_{\max} \sim 4$  keV are also observed.

**Fig. 5b.** A plot of the integral of  $\int \mathbf{E} \cdot d\mathbf{L}$  along the Polar spacecraft trajectory. At least three regions of field reversal are seen.

A limited amount of EFW electric field data and ion (CIS) data was analyzed for these passes. In Fig. 7 we show a plot of the CIS data from C4. The top panel is an energy-vs-time spectrogram with  $H^+$  energy flux color-coded. The middle and bottom panels display the pitch angle distribution for  $H^+$  and  $O^+$ , respectively. The plot shows significant  $H^+$  fluxes beginning near 07:17:30 UT, in agreement with the PEACE electron data of Fig. 6c. Periods of dominant upward  $H^+$  flux (pitch angles  $>90$  degrees) occur in the approximate intervals 07:20:00 to 07:22:30 UT and after 07:24 UT. These periods would indicate an upward DC electric field beneath the satellite and therefore a region of inverted-V. In Fig. 8 we show three contours of differential energy flux integrated over the time interval 07:20:13 to 07:22:26 for the C4 spacecraft. The coordinate system is GSE and the blue arrow indicates the direction of the magnetic field. It is apparent in the second and third panels that most flux is observed to move in the anti-Earthward ( $-B$ ) direction with a median energy of over 300 eV. In Fig. 9 we show three contours of the distribution function as measured by CIS on C4 with units shown on the color bar. The observation time is 07:22:14 to 07:22:18. The coordinate system is “B parallel V” or BPV, with the magnetic field in the  $+z$  direction. The center and right panels both include the z-axis and indicate dominant flux in the anti-Earthward direction with a maximum energy in excess of 350 eV.

In Fig. 10 we show a plot of EFW electric field intensity measured on C4 for the 3 spacecraft axes, with x and y nearly (within a few degrees) perpendicular to the magnetic field. The figure indicates rather significant perpendicular electric fields (up to 100 mV/m) near 07:20:20 UT and again centered near 07:21:20 UT. These fields are consistent with a parallel electric field between those time periods, agreeing with the observation of upward  $H^+$  ions observed during this time interval by CIS.

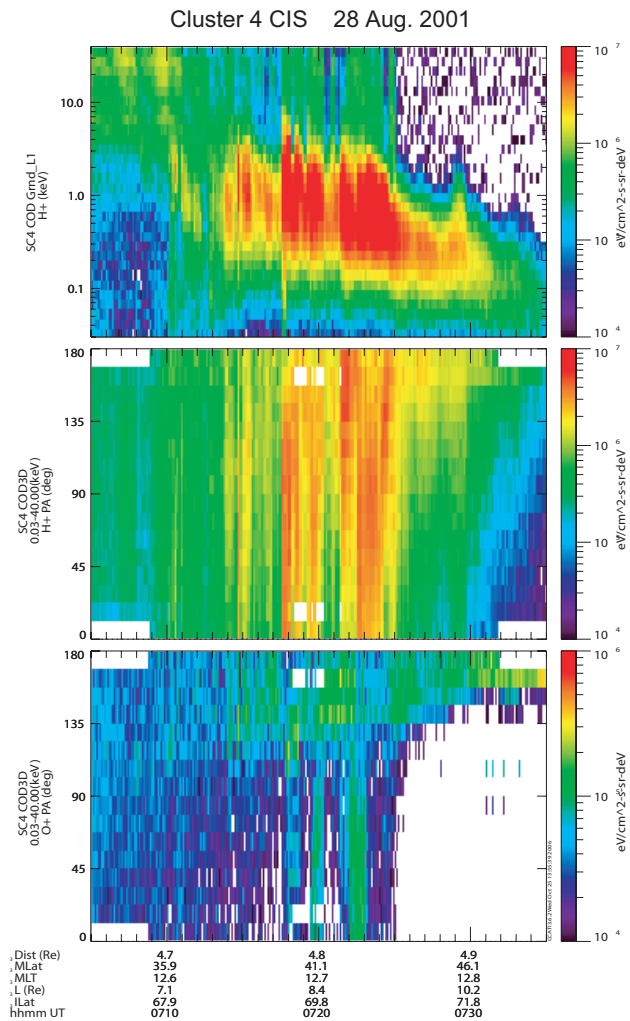

**Fig. 6.** Cluster C1, C2, and C4 PEACE electron data are displayed in panels (a–c) for the approximate time interval 07:00 UT–07:30 UT. The format for the panels (top to bottom) is energy flux for downward, trapped (90° pitch angle), and upward electrons.

Electric fields measured by EFW for each spacecraft of Cluster were obtained for times between 07:20 UT and 07:30 UT. The most significant perpendicular electric fields during this time were measured at the C2 spacecraft near 07:20:30 UT with amplitudes of  $\pm 100$  mV/m. Strong  $E_{\perp}$ , with magnitudes of  $\pm 100$  mV/m, were also measured at the C4 spacecraft with peaks in the range  $-125$  mV/m  $< E_{\perp} < 125$  mV/m in the time interval 07:21:20 UT to 07:21:30 UT. These fields compare with peak  $E_{\perp}$  measured by the EFI on the Polar spacecraft of  $\sim 400$  to 500 mV/m, and are consistent with the conservation of the first adiabatic invariant. In Fig. 11 we have plotted the projection along the spacecraft trajectory of the electric field measured by EFW on C4 at a higher resolution over the reduced time interval from 07:20:00 to 07:23:00. The second panel

contains the potential integrated along the spacecraft trajectory. Note that there are two regions where the integrated potential curve flattens and becomes slightly positive in slope – once near 07:21:20 and also near 07:21:50. In each case the net change in potential is less than 150 volts. However, to obtain these data, since there is no direct measurement of  $E_{\parallel}$ , the assumption is made that  $E_{\parallel} = 0$ . It is therefore possible that a more significant increase in the potential is actually present than is calculated.

Field-aligned currents typically observed in the auroral regions and current layers are necessary precursors for reconnection. The strongest downward currents for C1 occur in the time interval from about 07:19:30 UT to 07:20:30 UT with current densities calculated from the electron flux to be about  $-0.04 \mu\text{amps/m}^2$  (downward electrons). This is to

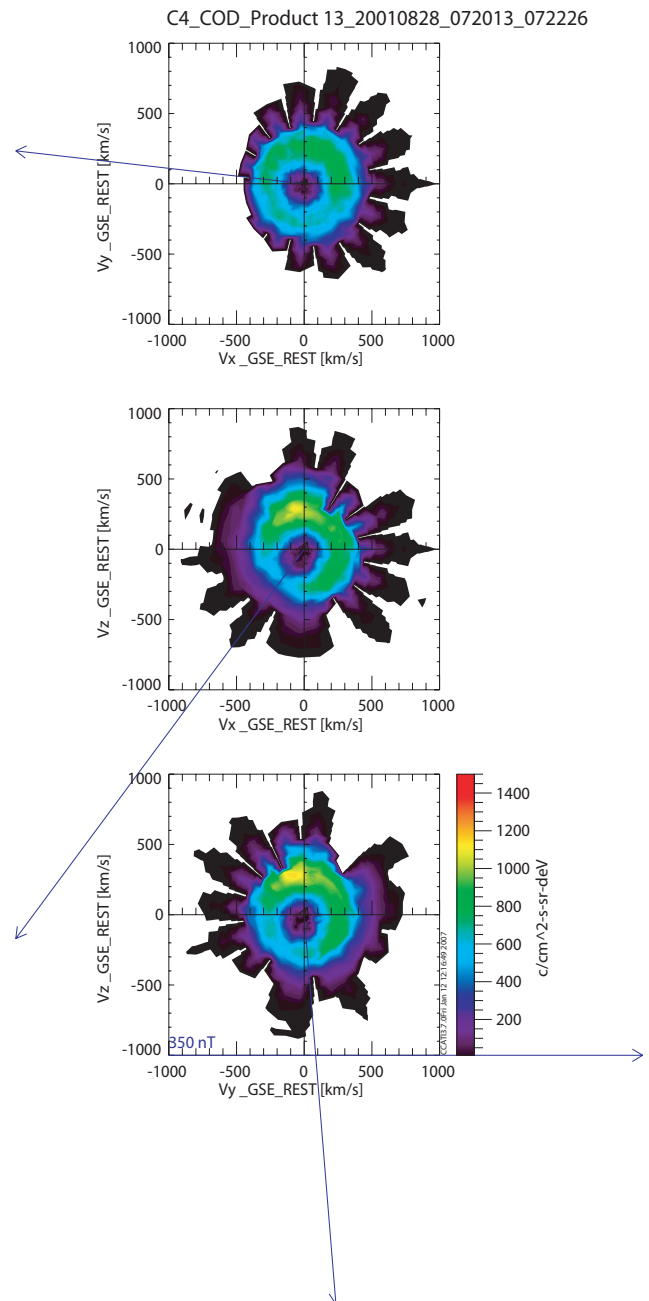

**Fig. 7.** A plot of the CIS data from C4. The top panel is an energy-vs-time spectrogram with H<sup>+</sup> energy flux color-coded. The middle and bottom panels display the pitch angle distribution for H<sup>+</sup> and O<sup>+</sup>, respectively.

be compared to  $\sim -0.27 \mu\text{amps/m}^2$  calculated at the altitude of the Polar spacecraft. The C2 satellite records the largest upward currents due to the spiky, beam-like upward electrons observed near 07:20 UT as downward currents (upward electrons) approaching  $0.2 \mu\text{amps/m}^2$  for 2 bursts of upward electrons are seen. We plot these current densities from PEACE electrons on the C1, C2, and C3 spacecraft in Fig. 12.

The time of nearest conjunction between the Polar spacecraft and the Cluster-4 (Cluster-2, Cluster-1) spacecraft is approximately 07:21 UT (07:24 UT, 07:25 UT). In Table 1 we list the coordinates of each spacecraft at these times.

At the same latitude position where the Polar spacecraft measures the peak of the inverted-V ( $IL=74.4^\circ$ ,  $2.6 R_E$ ,  $MLT=12.99$  h at 07:26:45 UT), the Cluster-1 spacecraft at 07:06:39 UT ( $MLT=12.84$  h), the Cluster-2 spacecraft at

**Fig. 8.** Contours of the differential energy flux (units shown on the color bar) observed by CIS on the C4 spacecraft integrated over the time interval 07:20:13 to 07:22:26. The axes are GSE coordinates and the blue arrow indicates the direction of the magnetic field.

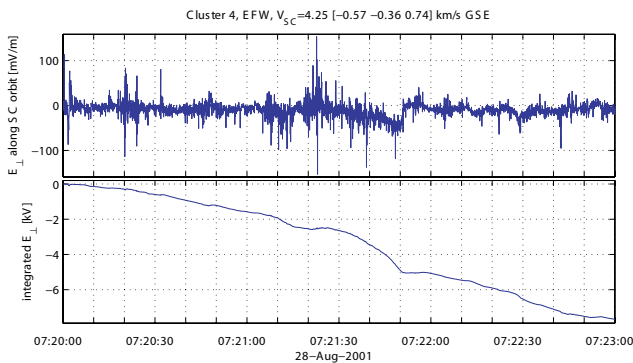

07:03:56 UT ( $MLT=12.77$  h), and the Cluster-4 spacecraft at 07:01:06 UT ( $MLT=12.82$  h) all are measuring high energy plasma in the auroral region, equatorward of the cusp. The DSIV is not observed by the Cluster satellites until  $IL \sim 76^\circ$ , which occurs about 10 min before the Polar spacecraft.

**Fig. 9.** Contours of the distribution function (units shown on the color bar) observed by CIS on C4 for the time interval 07:22:14 to 07:22:18. The coordinate system is BPV (B-parallel-v) with the magnetic field along the +z axis.

**Fig. 10.** A plot of EFW electric field intensity for C4 for the 3 spacecraft axes, with x and y nearly perpendicular to the magnetic field. The figure indicates rather significant perpendicular electric fields ( $\sim 100$  mV/m) near 07:20:20 UT and again centered near 07:21:20 UT.

**Fig. 11.** The top panel is the projection of the electric field measured by EFW along the C4 spacecraft trajectory. The data are at a higher resolution than shown in Fig. 10. The second panel is the integral of this electric field along the spacecraft trajectory.

## 5 Summary and conclusions

An example of a cusp conjunction between the Polar and Cluster spacecraft during a dayside inverted-V has been presented. The data indicate that significant field-aligned electric fields and currents exist in the cusp boundary layer as observed by the Polar spacecraft for  $r < 3 R_E$ . At the same time,

**Table 1.** Conjunction coordinates.

Time	Sat	IL (degs)	r ( $R_E$ )	MLT (h)
07:21 UT	POLAR	77.8	2.79	12.77
07:21 UT	C-4	77.8	5.35	13.10
07:24 UT	POLAR	76.1	2.69	12.90
07:24 UT	C-2	77.7	5.47	13.01
07:25 UT	POLAR	75.5	2.60	12.93
07:25 UT	C-1	77.4	5.58	13.02

the Cluster spacecraft, (for  $r > 5 R_E$  along the same or near-conjunctive magnetic field line), observes electron acceleration with somewhat smaller energies and electric fields of the same sense as observed at lower altitudes by instruments on the Polar spacecraft. The electric field of the DSIV between the Polar and Cluster spacecraft appears to be directed upward with a magnitude of approximately  $500 \text{ V} < E < 1.0 \text{ kV}$ , consistent with observed  $E_{\text{max}}$  for electrons observed by the Polar HYDRA and the Cluster PEACE.

As observed most prominently at the C2 spacecraft, a region of upward electrons in the cusp boundary layer is observed equatorward of the DSIV. The region is likely a return current region that is observed at the Polar spacecraft,

poleward of the DSIV. This indicates that a complex 3-dimensional structure is intertwined throughout the region, which may also exhibit temporal effects.

Significant values of  $E_{\perp}$  are observed by the EFI on board the Polar spacecraft indicating a moderate  $E_{\parallel}$  beneath the spacecraft. The source of this electric field may be a reconnection site located along the magnetic field at higher altitudes that at least partially closes near the Polar spacecraft and extends to lower altitude (cf. McFadden et al., 1999). Mozer et al. (2004) have observed large amplitude, extremely rapid, predominantly perpendicular electric field structures at the magnetopause that may be associated with reconnection regions. It is possible that such strong localized electric fields map to lower altitudes and form the parallel and perpendicular electric fields that are observed at Polar altitudes. Additionally, Alfvén waves that may be associated with reconnection events have been identified by the Polar plasma wave instrument at some DSIVs (Figs. 1 and 2).

Ion data from the CIS confirm the location of the cusp boundary layer observed by the Cluster spacecraft. Periods of dominant upward  $H^+$  flux (pitch angles  $>90$  degrees) occur in the approximate interval 07:20:00 to 07:22:30 UT, where precipitating electrons are also observed, thus indicating an upward DC electric field beneath the satellite and therefore a region of inverted-V. In addition, the CIS data measured from the C1 spacecraft (not shown) indicate an onset of predominately downward  $H^+$  flux and bi-directional  $O^+$  flux at 07:19:30 UT. This gives way to predominately upward  $H^+$  and  $O^+$  flux in the interval from 07:20 UT to 07:21 UT when the PEACE electrons indicate enhanced downward electron flux.

Although the conjunction between the Polar and Cluster spacecraft is not perfect in time, it is close spatially. The cusp boundary layer (CBL) is encountered by the Polar spacecraft at  $\sim 07:28$  UT at  $IL=73.5^{\circ}$ ,  $MLT=13.02$ , while the C1 spacecraft encounters this boundary near 07:18 UT at  $IL\approx 76^{\circ}$ ,  $MLT=13.07$ , over 10 min later. As shown by Marklund et al. (2004), significant changes in the region mapping to auroral acceleration can occur over timescales of  $\sim 200$  s. The fact that the CBL is located at approximately the same MLT and IL, however, indicates the spatial boundary is approximately steady. At the time of conjunction, the Polar spacecraft is between 2.5 and 3.0  $R_E$  below C1, C2, and C4. The order of orbit of the Cluster spacecraft was C4, C2, and C1. The first significant plasma boundary of field-aligned electrons encountered by C4 occurred about 07:17:30 UT ( $IL\sim 77.34^{\circ}$ ). Flux levels were somewhat less intense, but C2 encountered a similar plasma boundary near 07:17:00 UT ( $IL\sim 76.73^{\circ}$ ). C1 experienced significant upward electron beams as early as 07:14:30 UT, and again near 07:18:30 UT, but enhanced, precipitating electrons were not encountered until 07:19:30 UT ( $IL\sim 76.52^{\circ}$ ). It appears that the plasma boundary thus moved to lower invariant latitudes. Assuming the boundary experienced by C4 at 07:17:30 UT was the same (moving) boundary experienced by C4 at 07:19:30 UT,

**Fig. 12.** Current densities determined from the C1, C2, and C4 PEACE electron data. The units are amps/m<sup>2</sup>.

we estimate the velocity of this boundary to be about 4 km/s equatorward. Based on spacecraft velocity at the time of conjunction, the inverted-V encountered by Polar had an approximate extent perpendicular to the magnetic field of 900 km. Spacecraft C4 encountered an inverted-V region (between 07:20–07:22:30 UT) with a perpendicular extent of about 400 km. We conclude that a parallel electric field extends between the Polar and Cluster satellites. While reconnection likely takes place at higher altitude along field lines that may map to the DSIV, there is no clear evidence from the data examined here that such a mapping exists. It will be important in the future to find an example of Cluster within a reconnection site and a conjugate satellite at much lower altitude.

Unfortunately small changes in time and space for these conjunctions can lead to significant effects in mapping the magnetic field lines, particularly when the two spacecraft are well separated in altitude. We look forward to examining additional data for conjunctions between Cluster and Polar to determine a possible relationship of the dayside inverted-Vs to reconnection regions.

*Acknowledgements.* We wish to thank all the investigators who have contributed data to this study: J. D. Scudder (Polar HYDRA); H. Réme (Cluster, CIS); A. Fazakerley (Cluster PEACE); M. Andre (Cluster EFW); C. T. Russell (Polar MFI); and E. Lucek (Cluster FGM). We also thank J. Hospodarsky for clerical assistance.
