**Abstract.** Day-to-day fluctuations of the daily range of the geomagnetic field  $H$  at the equatorial electrojet stations Ancon (ANC, 77.0° W) and Sao Luis (SLZ, 44.2° W) are described for the period January–June 1993. The  $H$  field started increasing between midnight and sunrise, reaching a peak shortly before noon. The daily range of  $H$  was maximum during March and April and minimum during June. Regardless of the month, the range in  $H$  was significantly larger at ANC than at SLZ. The 27-day running mean of the range of  $H$  varied from 80 nT to 125 nT at SLZ and from 105 nT to 180 nT at ANC. The day-to-day values of the range of  $H$  showed very faithful variations at the two stations. The deviations of the daily range of  $H$  from its 27-day running mean values showed good correlation between the two stations. Some large storm-time effects were seen at both stations. The correlation was still significant, when data were corrected for  $D_{st}$  index values. It is suggested that the range in  $H$  at the two electrojet stations, separated by more than 2000 km, are affected by some common sources other than the ring current, which need to be identified. Spectral analysis of the range of  $H$  shows remarkable similarity at the two stations, with a dominant period of 15 days at both stations.

**Keywords.** Ionosphere (Electric fields and currents; Equatorial ionosphere; Ionosphere-atmosphere interactions)

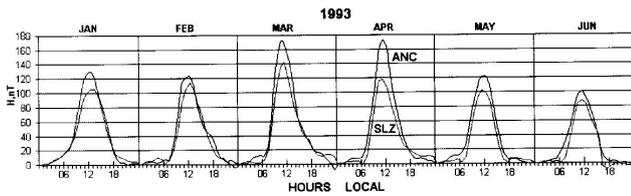

### 1 Introduction

The daily variations of the Earth's magnetic field at the ground stations were suggested by Stewart (1882) as due to the movement of the conducting upper atmosphere across the vertical component of the Earth's magnetic field arising due to the solar heating of the atmosphere. Chapman (1919) suggested that the regular tidal movement of the at-

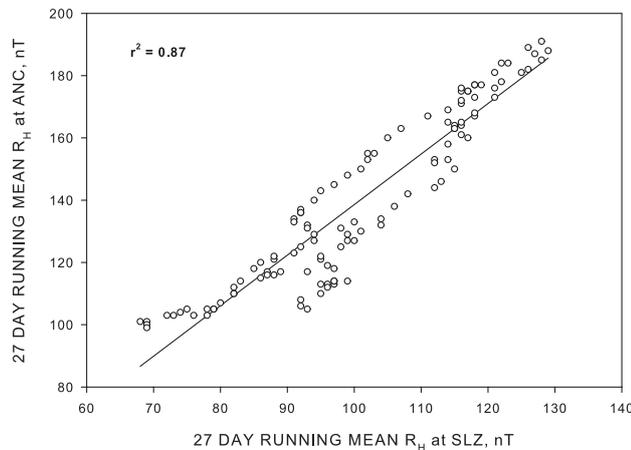

mosphere across the Earth's magnetic field generates a regular pattern of electric field in the upper atmosphere, which causes currents that produce regular magnetic field variations at the ground. The discovery of the enhancement in the daily variation of the horizontal field,  $H$ , within a narrow belt of latitudes over the equator (Egedal, 1947), was explained by Chapman (1951) as due to an eastward current in the E-region of the ionosphere with a latitude belt of  $\pm 3^\circ$  centered over the dip equator. This phenomenon, known as equatorial electrojet (EEJ), could not be explained by assuming an enhancement of either the electric field or the electron density over the dip equator. Cowling and Borger (1948) suggested that under the situation of orthogonal magnetic and electric fields over the dip equator, a vertical Hall polarization field would be generated, which would result in an abnormal increase in the electric conductivity over the magnetic equator. Thus, the same Sq electric field at low latitudes outside the electrojet belt can cause a larger current over the magnetic equator due to increased electric conductivity (Baker and Martyn, 1953).

The equatorial electrojet depends both on the maximum electron density of the E-region,  $N_m E$ , as well as the electric field  $E$ . Rastogi (1993) showed that the solar cycle variation of the daily range of  $H$ ,  $R_H$  at Huancayo and Kodaikanal depend mostly on the corresponding variation of  $N_m E$ , with little effect from any variation of the electric field. The seasonal variation of  $R_H$  after correction due to the variation of  $N_m E$  depends on the corresponding variations in the electric field. The daily variation of  $R_H$  depends on the product of  $N_m E$  and  $E$ . The equatorial electrojet is affected by a temporary increase in the ionization during solar flares, increasing  $\Delta H$  during normal and decreasing it during counter-electrojet periods (Rastogi, 1999, and references therein). Slowly varying, as well as rapidly changing parameters of solar wind cause an imposition of the electric field on the equatorial ionosphere, thus triggering changes in the equatorial electrojet (Rastogi, 2006).

**Fig. 1b.** Mass plot of the 27-day running mean values of the daily range in H at ANC plotted against values at SLZ.

Soon after the discovery of EEJ, measurements of H at the equatorial stations were made in India (Pramanik and Yagna Narayan, 1952) and in Nigeria (Onwumechilli, 1959). Establishment of additional electrojet stations during IGY enabled Rastogi (1962) to identify a significant longitudinal variation in the strength of the electrojet with a maximum at 75° W and a minimum along 75° E longitudes. Kane (1982) described the comparison of mean daily variations of H, D and Z at Huancayo (12° S, 75° W, dip 1.9°) and Eusebio (4° S, 39° W, dip -3.5°). Recently, Doumouya et al. (2003) have described the local time and longitude dependence of EEJ at a number of stations operating during IEEY. No major efforts seem to have been made on the day-to-day variations of the range in H ( $R_H$ ) at two electrojet stations. In this paper we compare the day-to-day variations of  $R_H$  and the range in H (pointing to magnetic north) at Ancon in Peru and Sao Luis in Brazil, during the period January to June 1993. The geographic coordinates and the geomagnetic parameters of the two stations for March 1993 are listed in Table 1. The two stations are separated by 33° in longitude. The inclination is 1.21° N at Ancon and 0.25° S at Sao Luis.

## 2 Results

The data were first cleaned up for gaps and sudden changes in the base level. Only complete day series were taken for further analysis. Daily variations of the H component were averaged over the five quietest days of each of the months in this period for both the stations. The Sq-H variations are taken as the daily variations of the deviations of H with respect to 0.5h local time value. The quiet day mean Sq-H variations at ANC and SLZ for each month are shown in Fig. 1a. During any of the months, the daily range in H was larger at ANC than at SLZ. Further, as expected of an equatorial station, the daily range in H at any of the stations was largest in the equinoctial months of March and lowest during the local winter month of June.

To obtain a better estimate of the relation between the daily ranges in H at the two stations, 27-day running averages were computed and the mass plot of the running mean values of the daily range in H at the two stations are shown in Fig. 1b. The daily range in H varied from 80 to 125 nT at SLZ and from 105 to 180 nT at ANC. Thus, the changes were 45 nT at SLZ and 75 nT at ANC. The regression line for the linear fit and the correlation coefficient are also indicated in the figure (also provided in Table 2). A linear relation between the values of the daily range in H at the two stations is clearly seen. The slope is 1.83 and the intercept on the y-axis is -46 nT. The correlation coefficient is 0.87 ( $r^2=0.76$ ). A high correlation between the 27-day running mean values at the two stations is expected as the fluctuations like day-to-day variations will be removed in the running mean.

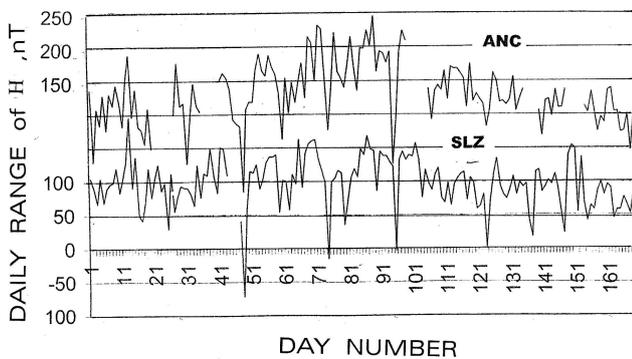

Figure 2a shows day-to-day variations of the daily range in H at ANC and SLZ for the period January–June 1993. The day number of the year is also marked in the figure. The fluctuations in the daily range of H are similar at the two stations. For Ancon the daily range in H varies mostly from 100 nT to more than 200 nT during March–April and from 50 nT to 150 nT during the other months. For Sao Luis most of the

$R_H$ at SLZ and at ANC	48	0.88	0.63
Deviations from running mean of $R_H$ at SLZ and at ANC	-1	0.58	0.45

**Fig. 2a.** Day-to-day variations of the daily ranges of H at ANC and SLZ for the period January to June 1993.

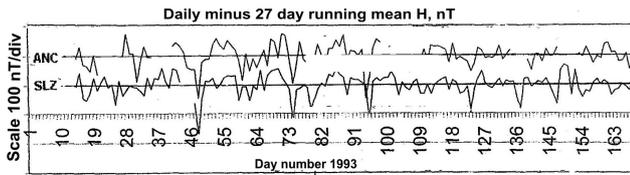

**Fig. 2b.** Mass plot of the daily range of H at ANC plotted against the values at SLZ.

values range from 50 nT to 150 nT. There are few negative or close to zero values, which are on geomagnetic disturbed periods. The mass plot of the daily range of H at ANC versus the daily range of H at SLZ is shown in Fig. 2b. The regression line for the linear fit and the correlation coefficient are also indicated in the figure. Significant correlation (.65) is seen in day-to-day variations of the daily range in H at the two stations that are separated by a distance over 2000 km. The slope is 0.77 and the intercept 60 nT. It is to be noted that the correlation improves if the few points with very low values at one station and values high at the other station are removed. Rastogi (2005) compared the day-to-day fluctuations in the daily range of H at Tirunelveli in India and Bac-Lieu in Vietnam, two stations close to the dip equator but separated by 28° in longitudes, and found similar variations.

The 27-day running mean values were subtracted from the individual values and deviations obtained. This will remove the seasonal variation. The day-to-day variations of the deviations in the range in H at the two stations are shown in Fig. 3a. The values at the two stations are also shown in Fig. 3b as a mass plot along with the regression line for best linear fit and the correlation. Smaller values of the range in

H are negative here after subtracting the running mean. Significant correlation (0.67) is seen between the daily ranges in H at the two stations after subtracting the 27-day running mean. A few points with large deviations in the range H seem to be due to disturbed days. To remove the disturbance ring current effect, the  $D_{st}$  indices were subtracted corresponding to the two stations. Mass plots of the daily ranges in H after subtracting the 27-day running mean and  $D_{st}$  index values at the two stations are shown in Fig. 4. Good correlation (0.5) between the values of the daily range in H at the two stations after subtracting the 27-day running mean and disturbance index is still seen.

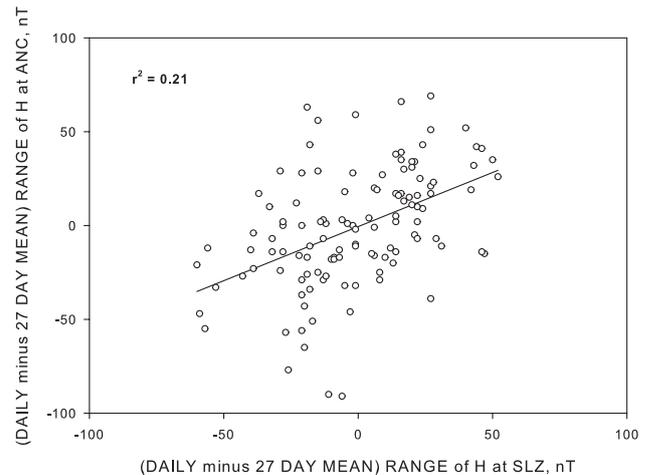

Thus, the daily ranges in H at the two equatorial stations separated by more than 2000 km show good correlation after subtracting the mean (27-day running mean) ionospheric current ( $Sq$ ) and the ring current ( $D_{st}$ ). This suggests that there is a source of electric field over the equatorial ionosphere that is of a global scale rather than local extent. The day-to-day fluctuations in the daily range of H could be

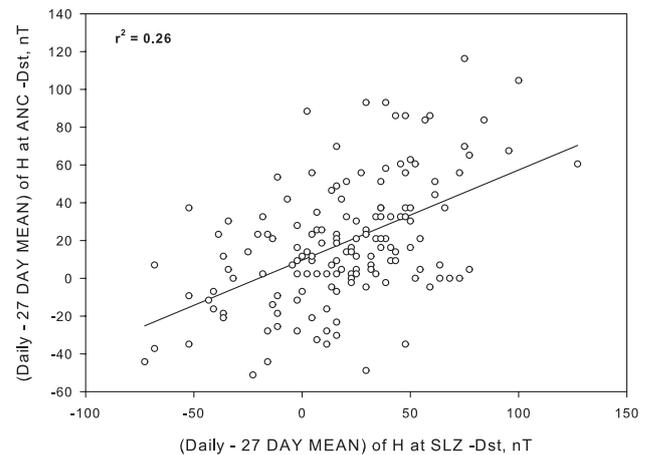

**Fig. 3a.** Day-to-day variations of the daily ranges of H at ANC and SLZ after removing the 27-day running mean plotted for the period January to June 1993.

due to the day-to-day changes in the electric field caused by changes in the neutral winds. Planetary waves of periods 2 d, 5 d, 10 d and 15 d have been identified in neutral winds in the upper mesosphere. Kovalam et al. (1999) reported peaks at 6.5 d, 3.5 d and 2.5 d from the power spectral studies of winds (86–92 km) from the MF-spaced receiver measurements at Pontianak (0° N, 109° E) and Christmas Island (2° N, 157° W). Cross-spectral studies of the winds at the two locations also provided the direction of propagation of planetary waves from the phase differences. Harmonic analysis using band-pass filtering of hourly data showed amplitudes of 3.5 d and 6.5 d waves up to 30 m/s. Similar studies from Tirunelveli (8.7° N, 77.8° E) showed 5.3d, 3.5d and quasi 2-D waves (Gurubaran et al., 2001; Sridharan et al., 2002). Periodicities ranging from 2 days to about 20 days have been reported in equatorial electrojet (Ramkumar et al., 2006, and references therein). Signatures of planetary waves have been observed in several ionospheric parameters. Forbes and Leveroni (1992) observed a quasi-16-day oscillation in equatorial E and F region parameters. The effects were interpreted in terms of electric fields induced by an ionospheric wind dynamo, and were attributed due to the upward penetration of a free Rossby mode excited in the stratosphere. Parish et al. (1994) reported oscillations with a periodicity in the range of 2–35 days from hourly  $\Delta H$  values. They argued that spectral peaks near 16 days might be due to the combined action of direct high-energy solar radiations and planetary waves propagating up from the lower atmosphere.

The time series of the daily ranges of H at the two stations after subtracting the 27-d running means were subjected to spectral analysis to obtain frequency components. Since there were a few gaps in the time series the method of Schulz and Statteger (1997) was employed, which can handle unevenly sampled data. Normalized periodograms are obtained from the harmonic analysis and the spectral power contained in each spectral element is normalized with respect to the total power contained in all spectral elements. Figure 5 shows the normalized periodograms for the two stations. Power (in fraction) is plotted against the period. Dotted lines show the 95% confidence level. A dominant period of 15 d is seen at both the stations. Smaller peaks at 3–4 d, 5.5 d and 7–9 d are also seen.

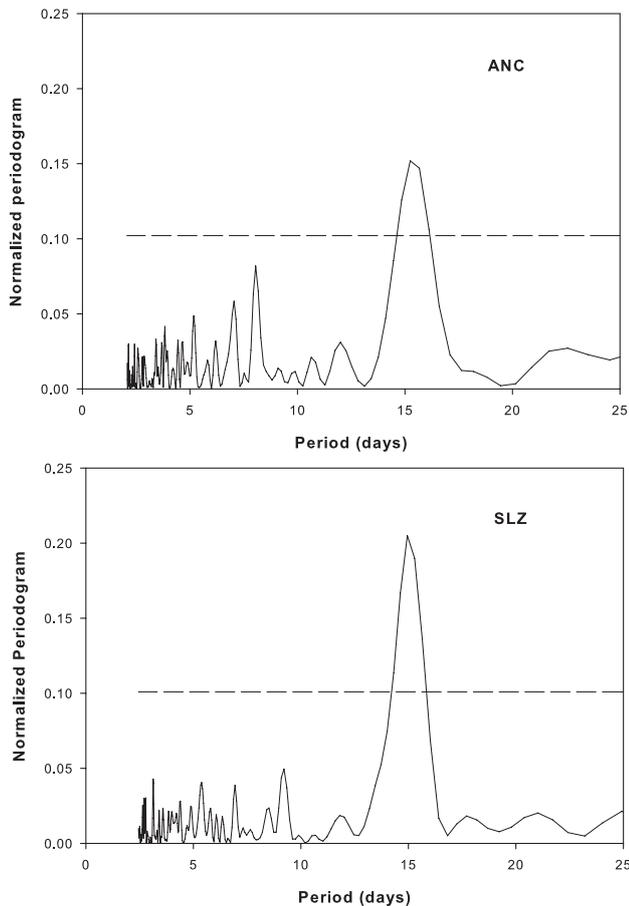

**Fig. 3b.** Mass plot of the daily range of H at ANC after removing the 27-day running mean plotted against the values at SLZ.

**Fig. 4.** Mass plot of the daily range of H at ANC after removing both the 27-day running mean and  $D_{st}$  plotted against similar values at SLZ.

### 3 Summary and conclusion

Day-to-day fluctuations of the daily range of the northward geomagnetic field H at the equatorial electrojet stations Ancon and Sao Luis for the period January–June 1993 show the range in H significantly larger at ANC than at SLZ during any of the months. The daily range of H was maximum during March and April and minimum during June. The day-to-day values of the range of H showed similar variations (correlation of 0.65) at the two stations. The deviations of the daily range of H from its 27-day running mean values also showed good correlation (0.67) between the two stations. The correlation was still significant (0.5), when data were corrected for  $D_{st}$  index values. It is suggested that the range in H at the two electrojet stations separated by more than 2000 km are affected by some common sources other

**Fig. 5.** Normalized periodograms for the de-trended (27-d) time series of the range of H at Ancon and Sao Luis (dashed line shows the 95% confidence limit).

than the ring current, which need to be identified. The day-to-day variations of the equatorial electrojet could also be due to extraterrestrial sources, like solar ionization radiation, solar wind velocity (Bhargava and Yacob, 1971) or due to interplanetary magnetic field strength and orientation (Rastogi and Chandra, 1974).

Spectral analysis of the range of H shows remarkable similarity at the two stations, with a dominant period of 15 days at both the stations. Smaller peaks at 3–4 d, 5.5 d and 7–9 d are also seen though below the confidence limit.

It is concluded that similar day-to-day variation of equatorial electrojet current at stations with varying separation be studied and the sources of such variations be sought in planetary waves, solar radiation and solar wind parameters.
