Abstract. A new class of solutions of the Vlasov-Maxwell equations is developed by means of generalization of the well-known Harris-Fadeev-Kan-Manankova family of exact two-dimensional equilibria. The new model reproduces the current sheet bending and shifting in the vertical plane, arising from the Earth dipole tilting and the solar wind non-radial propagation. The generalized model allows magnetic configurations with equatorial magnetic field decreasing in tailward direction as slow as $1/x$, contrary to the original Kan model ($1/x^3$); magnetic configurations with a single X-point are also available. The analytical solution is compared with the empirical T96 model in terms of the magnetic flux tube volume. It is found that parameters of the analytical model may be adjusted to fit a wide range of realistic current sheets. The best agreement between analytical and empirical models is obtained for the midtail at distances beyond $10 - 15 R_E$ at high levels of magnetospheric activity.

10 1 Introduction

Studies of magnetosphere dynamics, including substorm events, require a relevant current sheet (CS) stability analysis. This in turn requires a proper choice of the background magnetoplasma configuration. In applications to collisionless plasma, the background equilibrium is to be derived from a solution of the kinetic Vlasov-Maxwell equations. A number of such solutions are derived both numerically (e.g., Burkhardt et al., 1972; Pritchett and Coroniti, 1992; Cargill et al., 1994; Kuznetsova et al., 1995; Sitnov and Merkin, 2016; Vinogradov et al., 2016, and others), and analytically (e.g., Schindler and Birn, 2002; Yoon and Lui, 2005). All these solutions describe symmetric planar current sheets, the only approximate equilibrium solution for bent CS was introduced in the paper of Panov et al. (2012), where the authors present an analysis of direct THEMIS and GOES observations of plasma sheet evolution near substorm onset. Panov et al. (2012) have found the CS bending to be a source of the tailward growing normal magnetic field component B_z (in the current paper we use the reference system with x axis pointing tailward, y axis pointing downward, and z axis pointing north). Hence, bending of the current sheet turns out to be an important parameter for the sheet stability, controlled by the sign of the derivative $\partial B_z / \partial x$ (e.g., Hau et al., 1989; Erkaev et al., 2007, 2009; Pritchett and Coroniti, 2010) in many instances.

This result is in line with previous findings revealing that the configuration asymmetry can be an important factor of magnetosphere dynamics. Particularly, Kivelson and Hughes (1990) have first suggested that the CS bending may drop down the reconnection onset threshold. This idea was confirmed later, when Partamies et al. (2009) have noticed the seasonal variations in the number of substorm events with maximums in winter and summer periods, when dipole tilt angle is bigger (the known 5 geomagnetic activity maximums, e.g., in K_p index, are registered contrary around the equinoxes).

Later, this effect was investigated in details in the paper of Kubyshkina et al. (2015), where it was shown that the substorm probability is higher for about 10 – 25% during the periods with tilt angle $> 15^\circ$, as compared to the periods with smaller tilt angles. The direction of the solar wind (SW) flow also affects the substorm probability, it grows for 10 – 20% when SW flow direction enforces the CS tilt to increase. The statistical analysis has shown that the average substorm intensity (defined by 10 AL value during the event) is lower for larger effective tilts (dipole tilt angle plus solar wind flow inclination). In other words, a large number of weak substorms occur in those time intervals when effective tilt angles are high, and less number of more intense substorms is observed when tilt angles are small. This agrees also with the results of Nowada et al. (2009) study, where both AL and AU indices were analyzed for the intervals of negative interplanetary magnetic field B_z .

In the same paper of Kubyshkina et al. (2015), the dependence of magnetotail lobe magnetic field (as a proxy of the magnetic 15 flux) on the dipole tilt angle was studied by means of empirical modeling. The average lobe field was found to be smaller for all radial distances in a case of non-zero tilt angles, the decrease reached 10 – 20% for maximum tilt angle. This result is reasonable under the assumption that substorm onsets require a lower energy input during the periods of increased dipole tilt. Next, in the paper of Semenov et al. (2015) it was found that there is a clear dependence of the substorm probability on the 20 jumps of the z component of the SW velocity (asymmetric factor), while the jumps of number density or plasma pressure (symmetric factor) turn out to be noneffective. At last, we should note that the Earth's dipole tilt angle undergoes daily and seasonal variations in the interval of about $\pm 35^\circ$, so that it is equal to zero twice a day within about 4 months a year, and during other 8 months it is never zero. In addition, the solar wind flow direction varies for about $\pm 6^\circ$. These variations produce CS 25 inclination, bending and shift from the ecliptic plane. Therefore, the simplest solar wind-magnetosphere configuration (vertical dipole, planar CS, radial solar wind) adopted by the majority of models, is rather untypical and the development of the relevant asymmetric CS models is highly-demanded.

The first exact solution for two-dimensional (2D) equilibrium bent CS with non-zero dipole tilt was presented in short notes of Semenov et al. (2015). This solution generalizes the well-known Harris-Kan-Fadeev-Manakov family (see Yoon and Lui (2005)). In the present paper we investigate the obtained solution to estimate its relevance for the magnetotail CS 30 modeling and stability analysis. For this end, we compare the analytical asymmetric solution with the empirical Tsyganenko (1995) T96 model and define the analytical model parameters, providing the best agreement.

The paper is organized as follows. In section 2 we describe the analytical solution for asymmetric CS. In section 3 we compare analytical and empirical T96 solutions. In section 4 we present the further generalization of the analytical model, providing more realistic profiles of B_z in the equatorial plane. Discussion and conclusions finalize the paper in section 5.

2 Asymmetric solution

For two-component (proton+electron) isothermal plasma with Maxwellian distribution functions and constant current velocity the system of Vlasov-Maxwell equations can be reduced to the 2D Grad-Shafranov equation (see Schindler (1972); Yoon and Lui (2005)) for the dimensionless magnetic potential $\Psi = (0, \Psi, 0)$,

$$5 \quad \frac{\partial^2 \Psi}{\partial x^2} + \frac{\partial^2 \Psi}{\partial z^2} = e^{-2\Psi}. \quad (1)$$

The quantity Ψ is normalized for $(-B_0 L)$, where $L = 2cT_i/(eB_0V_i)$ is the typical length and $B_0 = \sqrt{8\pi n_0(T_e + T_i)}$ is the lobe magnetic field, $n_0 = n_{0e} = n_{0i}$ is the typical number density, $T_{e,i}$ are the electron and ion temperatures, respectively, and $V_{e,i}$ are the corresponding drift velocities, fulfilling the condition

$$V_i/T_i + V_e/T_e = 0. \quad (2)$$

10 Eq. (2) expresses the condition of the zero electrostatic potential. The model of an ion-dominated CS, where $|V_i/V_e| > T_i/T_e$ is considered in the paper of Yoon and Lui (2004). In the case of Maxwellian distribution functions condition (2) can be satisfied by means of the proper choice of the reference system, in general it cannot be fulfilled (Schindler and Birn (2002)).

A series of analytical solutions of Eq. (1) was found by Walker (1915), shown that the solution may be expressed via an arbitrary generating function g of the complex variable $\zeta = x + iz$,

$$15 \quad e^{-2\Psi} = \frac{4|g'|^2}{(1 + |g|^2)^2}, \quad g' = \frac{dg(\zeta)}{d\zeta}. \quad (3)$$

With the solution (3), the equilibrium magnetoplasma configuration takes the form

$$\Psi = \ln \left(\frac{1 + |g|^2}{2|g'|} \right), \quad (4)$$

$$n = \exp(-2\Psi), \quad p = 0.5 \exp(-2\Psi), \quad (5)$$

where p is the plasma pressure. By definition, the dimensionless magnetic field components are $B_x = -\partial\Psi/\partial z$ and $B_z = +\partial\Psi/\partial x$.

20 The particular choice of the generating function g specifies the particular CS model. In the current paper we consider the family of Harris-like models, including the classical Harris (1962) current sheet, the Fadeev et al. (1965) solution (Harris sheet complemented by an infinite chain of magnetic islands along the neutral plane), the Kan (1973) solution (Harris sheet with quasi-dipole), and the Manankova et al. (2000) solution, representing the combination of all previous models. The last one is 25 specified by the generating function

$$g(\zeta) = f + \sqrt{1 + f^2} \exp \left[i \left(\zeta - \frac{b}{\zeta - a} \right) \right]. \quad (6)$$

Solution (6) contains three real parameters a , b and f , where a specifies the shift along the x axis, b controls the field line elongation, and f defines the current density in the magnetic islands. Generating functions for other listed models are the

special cases of the function (6). Namely, one should set ($f = 0, a \neq 0, b \neq 0$) for the Kan solution; ($f \neq 0, a = b = 0$) for the Fadeev solution; and ($f = a = b = 0$) for the Harris solution.

The solution for asymmetric (bent) CS is developed in the paper of Semenov et al. (2015) by substituting the complex parameters $a \rightarrow ia$ and $b \rightarrow b_0 e^{i\varphi}$ in Eq. (6). The complex parameter a controls the shift of the CS in the z direction and φ controls the dipole tilt angle. For the case of asymmetric CS without plasmoids (Kan-like model, $f = 0$) the solution (6) takes relatively simple form,

$$\Psi = \ln \left(\frac{\cosh Z_*}{\sqrt{W}} \right), \quad (7)$$

$$Z_* = z - \frac{b_0 x \sin(\varphi) - b_0(z-a) \cos(\varphi)}{R^2}, \quad (8)$$

$$W = 1 + \frac{b_0^2 + 2b_0(x^2 - (z-a)^2) \cos(\varphi) + 4b_0 x(z-a) \sin(\varphi)}{R^4}, \quad (9)$$

where $R^2 = x^2 + (z-a)^2$. Asymmetric configurations of this type possess a dipole singularity at $(x, z) = (0, a)$ and two additional singularities at $(x, z) = (\pm\sqrt{b_0} \sin(\varphi/2), a \mp \sqrt{b_0} \cos(\varphi/2))$, rotating twice as slow as a dipole does. Hence, the effective dipole tilt is equal to $\varphi/2$. For positive tilt angles the CS is bent and uplifted over the ecliptic plane, and for negative tilts the CS is shifted down. The set of magnetic configurations for $\varphi/2 = \{0, 30, 60, 120\}$ degrees is shown in Fig 1. The two first cases (0° and 30°) can be observed in the Earth's magnetosphere, and other cases are shown here to illustrate the model behavior. The contribution of the parameter a is illustrated in Fig. 2, where magnetic configurations for $\varphi/2 = \{15^\circ, 30^\circ\}$ and $\Im(a) = \{2, 4\}$, respectively, are plotted.

Noteworthy, in the symmetric Kan model the X-point ($B_x = B_z = 0$) is located at infinity, but in asymmetric configurations the X-point starts to approach the dipole with increasing tilt angle. The X-point position as a function of φ is shown in Fig. 3 for three values of the parameter b_0 . For realistic values of $\varphi/2 \leq 30^\circ$ the X-point is still located in the distant tail (far beyond $60 R_E$), the approach to $14 R_E$ is achieved for $\varphi/2 = 60^\circ$. This X-point is not produced by magnetic reconnection, it is just an attribute of the bent CS steady state equilibrium. However, the appearance of the X-point can be considered as a manifestation of potentially unstable configuration. In such a case, the X-point motion towards dipole with increasing tilt angle could mean that CS evolves toward an unstable state.

3 Comparison with the T96 model

Topologically, magnetic configurations plotted in Fig. 2 are very similar to that of the Earth's magnetosphere. However, to estimate the relevance of the analytical solution one should compare some important numerical characteristics of the CS model with the corresponding values registered in real observations. This can be done utilizing empirical magnetic field models, providing realistic averaged magnetospheric configurations at various levels of magnetospheric activity. Of course, we should keep in mind that the real magnetosphere is an essentially three-dimensional structure. Following the dipole tilt (and solar wind flow direction) variations, the magnetotail CS bends and shifts from the equatorial plane in z direction (at most $\sim 3 R_E$ for maximum tilt) and also warps in the y direction. These effects are well-pronounced in empirical magnetospheric models, but

the 2D analytical model is evidently unable to reproduce all these complex deformations. Therefore, we restrict our study to the noon-midnight plane $y = 0$, and the two main effects manifested in that plane: CS bending and shifting in z direction.

To explore the appropriacy of the here presented analytical solution for asymmetric CS, we compare the predicted magnetic flux tube volume (a proxy for the entropy) with that calculated from the empirical model of Tsyganenko (1995) T96. We 5 consider the flux tube volume (FTV) instead of the entropy, since the analytical solution is isothermal. This quantity is chosen due to its importance for the magnetotail dynamics. As it was claimed by Birn et al. (2009) and verified by *in-situ* data analysis (Sergeev et al. (2014)), any bursty bulk flow (BBF), produced by reconnection in the magnetotail and moving toward the Earth, stops at that particular point, where the entropy of the ambient plasma is equal to that inside the BFF. The distribution of entropy along the magnetotail is also an important factor for the stability analysis (Birn et al. (2009)) and for the study of 10 wave (oscillations) generation and dissipation (Panov et al. (2016)).

The FTV is determined in the same way for both analytical and empirical models: we integrate dS/B along magnetic field lines, where dS is the field line length element and $B = \sqrt{B_x^2 + B_z^2}$. In the T96 model the location of the flux tube is computed by means of field line tracing, in the analytical model this is a curve of constant Ψ . As a first step, the values of FTV of a single flux tube are compared. The model parameters correspond to the quiet magnetospheric conditions with tilt angle of 30% 15 (see the legend of Fig. 5b). FTVs are calculated along the magnetic field line with a node at $(x, z) = (30, -2.4)$. To eliminate singularities, we excluded the near-Earth region $x < 5 R_E$, so that the total FTVs are calculated as $\int_{(30, -2.4)}^{(5, 1.5)} dS/B$. The results are shown in Fig. 4 by the blue curve for T96 and by red curve for the Kan model. The values of FTV, normalized for total FTV, are plotted as a function of x . It is seen that two models demonstrate rather close results. 90% of FTV are provided by the farther half of the tube, $x \in [15, 30] R_E$, and 50% of FTV are concentrated in the most distant interval within $3 - 4 R_E$ in 20 the x direction from the tube node.

Then, FTVs, calculated by means of analytical and empirical models, are compared at different levels of magnetospheric activity, characterized by input parameters of the T96 model (Dst index, the SW dynamical pressure, p_{dyn} , and SW magnetic field components B_y^{sw} and B_z^{sw}). Three sets of parameters are taken to specify the quiet magnetotail $\{Dst = -10, p_{dyn} = 2 \text{ nPa}, B_z^{sw} = 2 \text{ nT}\}$, substorm conditions $\{Dst = -50, p_{dyn} = 3 \text{ nPa}, B_z^{sw} = -3 \text{ nT}\}$, and storm $\{Dst = -150, p_{dyn} = 6 \text{ nPa}, B_z^{sw} = -7 \text{ nT}\}$. Magnetic field component B_y^{sw} was set equal to zero. Parameters a and b_0 of the analytical solution (7–9) are 25 found numerically to minimize the standard deviation between two models. The results (FTV versus x coordinate of the flux tube node) are presented in Fig. 5, where red lines plot analytical solutions and black ones plot the T96 results. The left column shows the symmetrical case (zero dipole tilt), and the right column corresponds to the dipole tilt angle of 30°.

One can see that the agreement between two models is quite good with the maximal standard deviations varying within 30 2 – 11%. The values of $d_{max} = \sigma_{max}/\langle FTV \rangle$ are given in legends of Fig. 5, where σ is the standard deviation and $\langle FTV \rangle$ is the average FTV. The better agreement is achieved for disturbed magnetospheric conditions, i.e. the analytical model describes the stretched CSs even better than the thicker ones. It is found that minimal difference between two models is obtained when parameter a is very close to the medium neutral sheet position determined from the empirical model. The best-fit value of the parameter b_0 , controlling the field lines stretching and the CS thinning, depends on the level of activity and the dipole tilt angle. It grows from 8.8 for the quiet magnetosphere to 51 for storm conditions. At any fixed distance, the stretching of 35

field lines makes the FTV to decrease with growing magnetospheric activity. E.g., at the distance of $x = 30 R_E$ it changes from $\approx 5 R_E/nT$ for "quiet" conditions to $\approx 3 R_E/nT$ for "substorm" conditions and to the $\approx 1.6 R_E/nT$ for "storm-time" conditions. Contrary, the asymmetric deformation of CS (dipole tilt angle) enforces the FTV to increase.

Fig. 5 shows a comparison of two models within the large interval $x \in [5, 30]$. To detect the best-match region we performed 5 the same analysis for eight short overlapping intervals $x \in [7.5, 12.5] + 2.5n$, where $n = 0, 1, \dots, 8$. The normalized standard deviation as a function of x_{0n} , where x_{0n} is the center of corresponding interval, is shown in Fig. 6, where three features are observed: (1) standard deviation grows toward the Earth and exceeds 10% for $x < 15 R_E$ for all activity levels; (2) deviations are bigger for the more quiet magnetosphere environment; (3) deviations are smaller for a tilt angle of 30° . As compared to results of the large interval analysis (Fig. 5), dependence on the activity level is the same, and dependence on the tilt angle 10 demonstrates opposite behavior. Overall, analytical and empirical models show good agreement beyond $15 R_E$, improving with growing activity.

4 Normal magnetic component

The results of the previous section show that parameters of the asymmetric Kan-like model may be adapted to provide rather 15 good agreement with the magnetotail CS, especially in a distant tail beyond $15 - 20 R_E$, and especially for bent current sheets. However, until now the practical usage of this model encountered the substantial obstacle, related to the behavior of the normal 20 magnetic field component. It can be easily checked that in the distant tail the Kan model yields $B_z \sim 1/x^3$, while in reality B_z decreases as $1/x$ or even slower (e.g., Behannon and Ness (1966); Mihalov et al. (1968); Behannon (1970); Wang and Lyons (2004); Yue et al. (2013)). This problem may be solved by introducing one more parameter in the generating function $g(\zeta)$. With the additional parameter n , general asymmetric model takes the form (compare to Eq. 16 of Yoon and Lui (2005))

$$g(\zeta) = f + \sqrt{1 + f^2} \exp \left[i \left(\zeta^n - \frac{b}{(\zeta - a)^k} \right) \right]. \quad (10)$$

Assuming $\{f, n, k\}$ to be real values, $a = a_1 + ia_2$, and $b = b_0 \exp(i\varphi)$, we derive

$$\Psi = \ln \left(\frac{f \cos X_* + \sqrt{1 + f^2} \cosh Z_*}{\sqrt{W}} \right), \quad (11)$$

$$X_* = r^n \cos(n\vartheta) - \frac{b_0}{R^k} \cos(k\Theta - \varphi), \quad (12)$$

$$Z_* = r^n \sin(n\vartheta) + \frac{b_0}{R^k} \sin(k\Theta - \varphi), \quad (13)$$

$$W = n^2 r^{2(n-1)} + \frac{b_0^2 k^2}{R^{2(k+1)}} + 2nkb_0 \frac{r^{n-1}}{R^{k+1}} \cos[(n-1)\vartheta + (k+1)\Theta - \varphi], \quad (14)$$

$$r = \sqrt{x^2 + z^2}, \quad \vartheta = \arctan \left(\frac{z}{x} \right), \quad (15)$$

$$R = \sqrt{(x - a_1)^2 + (z - a_2)^2}, \quad \theta = \arctan \left(\frac{z - a_2}{x - a_1} \right). \quad (16)$$

For symmetric Kan-like CS without plasmoids ($a = 0, f = 0, \varphi = 0$), the quantity B_z at the x axis takes the simple form $B_z(x, 0) = -(\partial W / \partial x) / (2W)$. It is seen that the Kan solution ($n = 1$) is the only degenerated case when the first term of W

turns to 1 and its derivative to zero, hence in the distant tail $B_z \sim (1/x^{2+k})$ due to the rightmost term of expression (14). For any $n \neq 1$ we have $(\partial W/\partial x)/W \sim 1/x$.

Parameter n controls flaring of magnetic field lines; values of $n > 1$ enforce strong convergence of the CS field lines toward the x axis, hence location of the X-line is drastically dependent on n . Sample Fig. 7 shows symmetric magnetic configurations (5 $a = 0, \varphi = 0, f = 0, b_0 = 1, k = 1$) for $n = \{0.95, 1, 1.05, 1.1\}$. In Fig. 8 reverse values of the equatorial magnetic field, $B_z^{-1}(x, 0)$, are plotted for several sets of the model parameters. It is seen that: a) all curves except the red one (original Kan solution, $n = 1$) tend to $O(1/x)$, b) numerical values of B_z are highly variable depending on different combinations of parameters $\{b_0, k, n\}$.

5 Discussion and conclusions

10 In empirical models (T89, T96, T01, TS05, etc.) magnetic field configurations with any plasma populations are not force-balanced since $\nabla \times [\mathbf{j} \times \mathbf{B}] \neq 0$, or there is no ∇P to balance Ampere's force (Zaharia et al. (2003)). That is why we crucially need kinetic force-balanced CS models for many magnetospheric studies, such as wave generation in plasma, CS stability analysis, and numerical simulations of magnetotail dynamics. So far these studies were restricted by purely symmetric background equilibria. In this paper we present the extension of the well-known family of exact kinetic Harris-Kan-Faddev-Manankova 15 solutions to the asymmetric 2D CS. This extension is really important, since the Earth dipole is tilted most of the time.

To validate the obtained analytic solution for asymmetric CS we performed a comparison with T96 model, used as a proxy of realistic averaged magnetospheric configuration. It is shown that the proposed model provides a reasonable approximation for the magnetotail CS in a wide range of dipole tilt angles and geomagnetic activity levels. Particularly, the parameters of the analytical model can ever be adjusted to fit the behavior of the magnetic FTV with an accuracy of about 10% for all distances 20 from 5 to 30 R_E tailward. For short segments ($5 R_E$) of the CS, located beyond $15 R_E$, the agreement may be improved up to 5% (except the case of the bent CS at quiet magnetospheric conditions). The agreement between analytical and empirical models is found to be better for the stretched magnetic configuration, i.e., for the pre-substorm conditions.

Notably, such a good agreement is obtained for the simplest three-parametric Kan-like model (7–9), where parameter a controls the CS displacement from the equatorial plane, parameter b_0 controls magnetic field lines stretching, and parameter φ 25 specifies the CS bending. For further studies the more general model (11–16) can be considered, where additional parameters n and k provide the more accurate adjustment of the magnetoplasma quantities. More over, for sub-Alfvénic plasma, i.e., for the low-activity periods, all model parameters may be treated as time-dependent quantities (Wolf (1983); Semenov et al. (2015)). The time-dependent approach in such a modeling is not appropriate for the periods of explosive activity, such as storms and substorms, when BBFs with Alfvénic speed are produced.

30 Of course, the suggested analytical model is still far from universality. One significant limitation of this model is related to the isothermal constraint. This constraint may be released for four-component (two positive + two negative) plasma with bi-Maxwellian distribution functions for each particle specie (Kan (1973); Voronina and Kan (1993)). In such a case the condition (2) takes the form $V_{ik}/T_{ik} + V_{ek}/T_{ek} = 0$, where $k = \{1, 2\}$. If two plasma components give zero contribution in the current

velocity, $V_{i2} - V_{e2} = 0$, the Eq. (1) stays valid for nonuniform plasma temperature (Voronina and Kan (1993)). In application to the Earth magnetotail studies this means that Kan-like models are to be best appropriate for high activity levels. Indeed, in the quiet magnetotail the population of ions $\{O^+, O^{++}, He^{++}\}$, penetrating from ionosphere, is less than 1% (Lennartsson et al. (1986)), hence the approximation of "proton+electron" plasma is relevant. In such a case the Kan-like model assumes isothermality, which is not reflected in observations (e.g., Kissinger et al., 2012; Wang et al., 2012). With the growth of geomagnetic activity, the O^+ contribution becomes essential during intensive storm events in a main and recovery phases, hence the isothermal constraint may be released. This conclusion is in line with the results of our study.

Other model limitations are the two-dimensionality, and isotropy of the plasma pressure. Even with these limitations, the model stays appropriate for the wide class of problems, mentioned in the beginning of the current section. Particularly, we lay hopes that application of the presented model can stimulate investigations on the magnetotail CS stability to resolve the question suggested by Kivelson and Hughes (1990): why symmetric CS can accumulate magnetic flux energy more effective, and does the threshold of substorm-initiating instability depend on degree of the CS bending.

In summary:

- An exact asymmetric 2D CS equilibrium is build by means of generalization of the Harris-Fadeev-Kan-Manankova family of symmetric solutions of the Vlasov-Maxwell equations. Our new model reproduces the effects, related to the Earth dipole tilt and CS bending; it also releases degeneracy of the original model, yielding too fast decrease of the normal magnetic component.
- Parameters of the asymmetric model may be adjusted to reproduce the realistic distribution of the magnetic flux tube volume at any level of geomagnetic activity; with enhancing activity the model relevance improves.
- The asymmetric solution does not contain any limitation for the tilt angle values, hence the model is appropriate for any Earth-like magnetosphere with arbitrary dipole inclination.
- The obtained bent CS solution contains the X-point, moving from infinity toward the dipole with the dipole tilt increase, staying still far beyond the lunar orbit for the Earth magnetotail realistic tilt angles. Much more effectively the location of the X-point is controlled by the new parameter n of the generalized model (11–16).

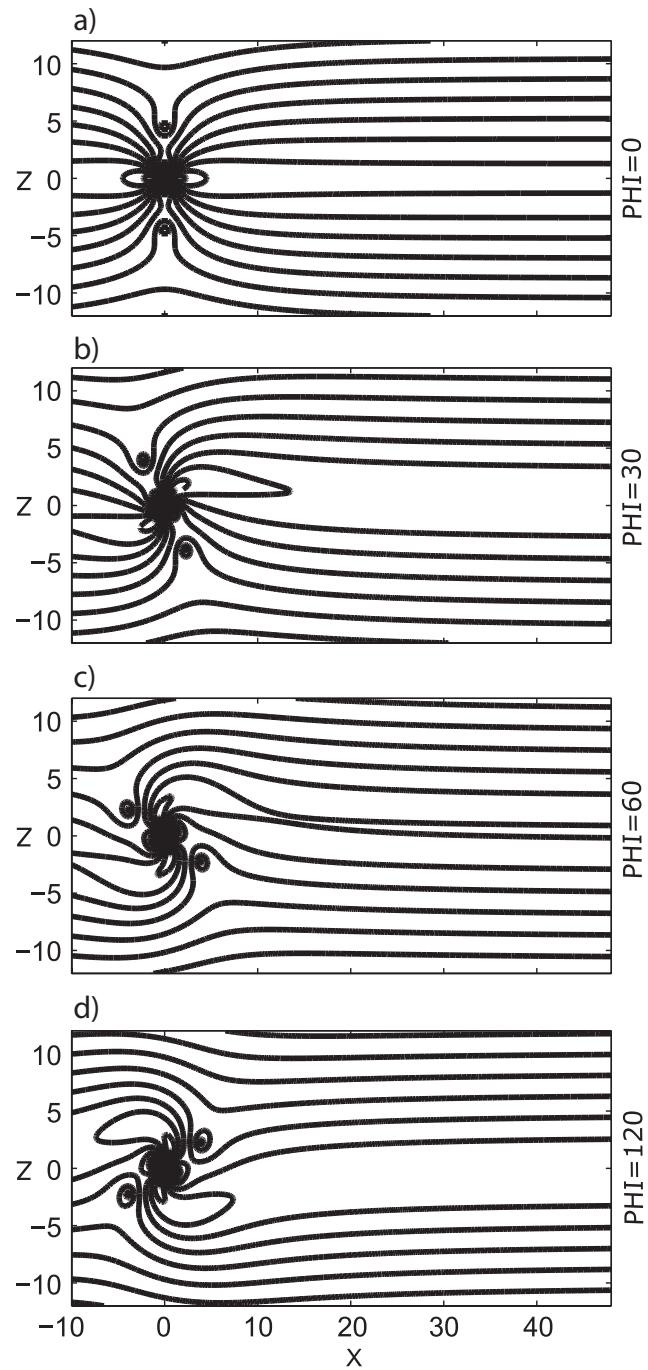

Figure 1. Magnetic field lines for asymmetric Kan model (7–9) with parameters $a = 0$ and $b_0 = 2$ for different effective tilt angles $\text{PHI} = \varphi/2 = \{0^\circ, 30^\circ, 60^\circ, 120^\circ\}$ are plotted at panels {a, b, c, d}, respectively. The length scale is $1 R_E$.

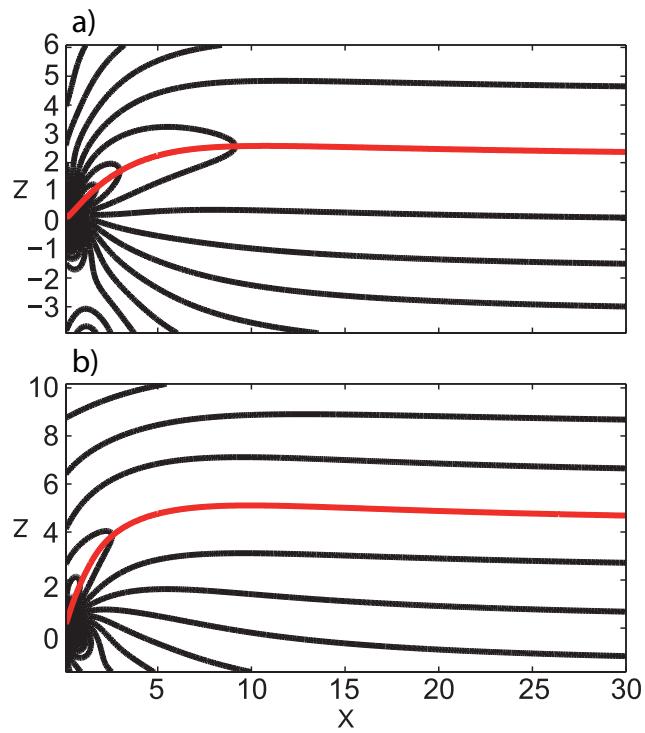

Figure 2. Magnetic field lines for asymmetric Kan model (7–9) for effective tilt angles $\varphi/2 = 15^\circ$ (top) and $\varphi/2 = 30^\circ$ (bottom) with $b_0 = 2$ and non-zero displacement parameters $\Im(a) = 2$ and $\Im(a) = 4$, respectively. Red curves show the "CS centers", defined as curves of minimal Ψ . The length scale is $1 R_E$.

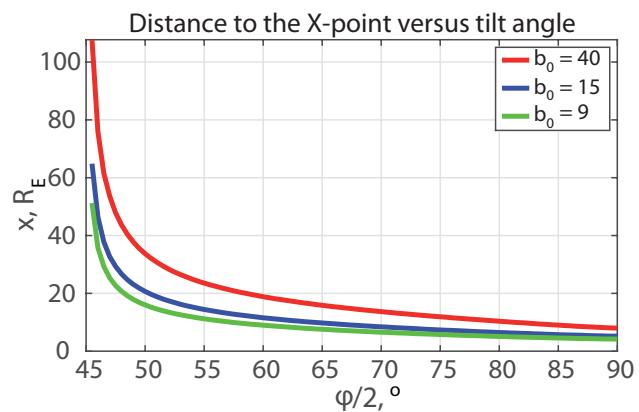

Figure 3. X-point location versus the effective tilt angle $\varphi/2$ in the asymmetric Kan solution (7–9) with $a = 0$ and parameter $b_0 = 40$ (red), $b_0 = 15$ (blue), and $b_0 = 9$ (green).

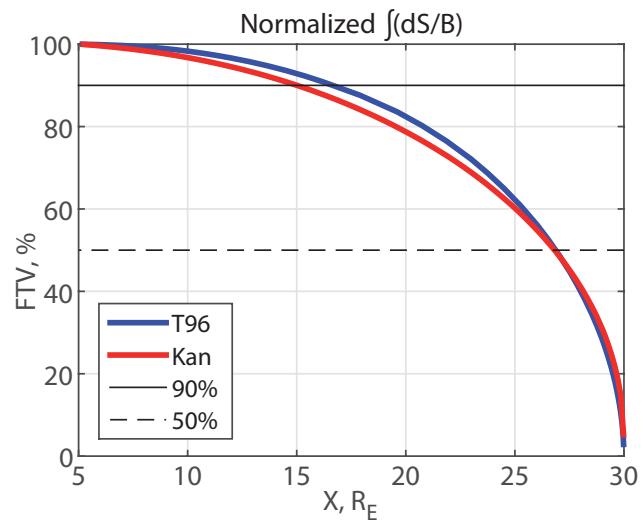

Figure 4. Flux tube volume $\int_{(30, -2.4)}^{(x, z)} (dS/B)$ normalized to the full FTV $\int_{(30, -2.4)}^{(5, 1.5)} (dS/B)$, in percents, calculated by T96 model (blue) and by the Kan model (red) for the quiet conditions with tilt angle $\phi/2 = 30^\circ$ (model parameters are given in the legend of Fig. 5b). The Earth is on the left.

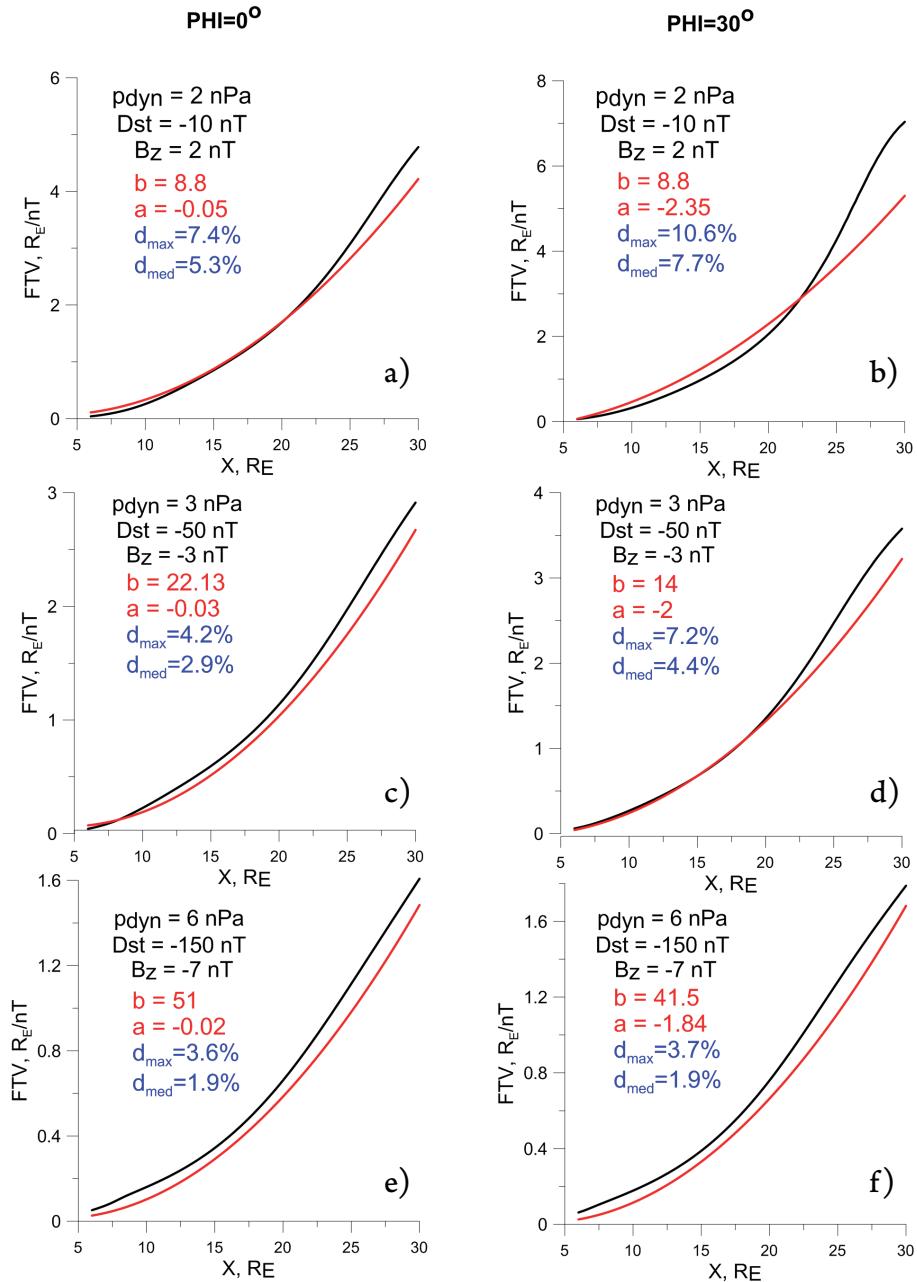

Figure 5. Flux tube volumes: analytical solution (red curves) and T96 (black curves) for quiet (top row), substorm (middle row) and storm (bottom row) conditions are plotted for tilt angles 0° (left column) and 30° (right column). Input parameters for the T96 model (black text), for the Kan-like model (red text), and standard deviations normalized for average FTV (blue text) are given in legends. The Earth is on the left.

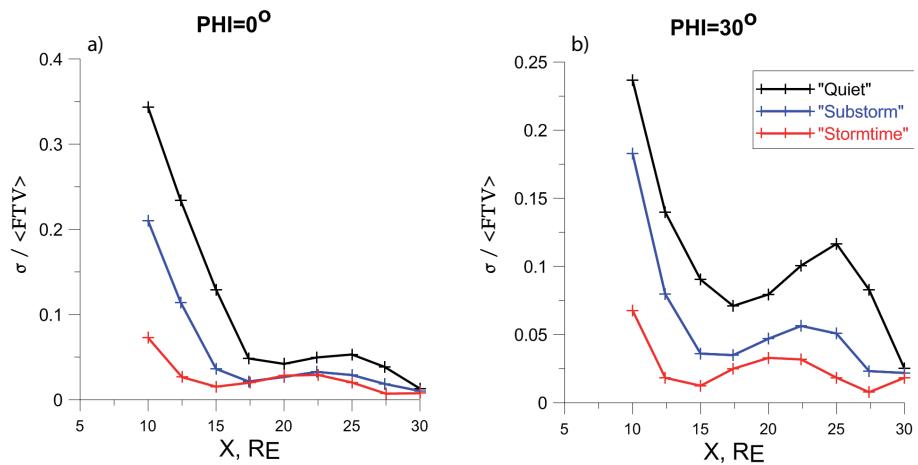

Figure 6. Comparison of analytical and empirical models for symmetric (dipole tilt 0° , on the left) and bent (30° , on the right) current sheets. Standard deviations, σ , normalized for average FTV, are shown as functions of x_0 , where x_0 is the center of the region under consideration $[x_0 - 2.5, x_0 + 2.5]$, for quiet (black curves), substorm (blue curves) and storm (red curves) conditions. The Earth is on the left.

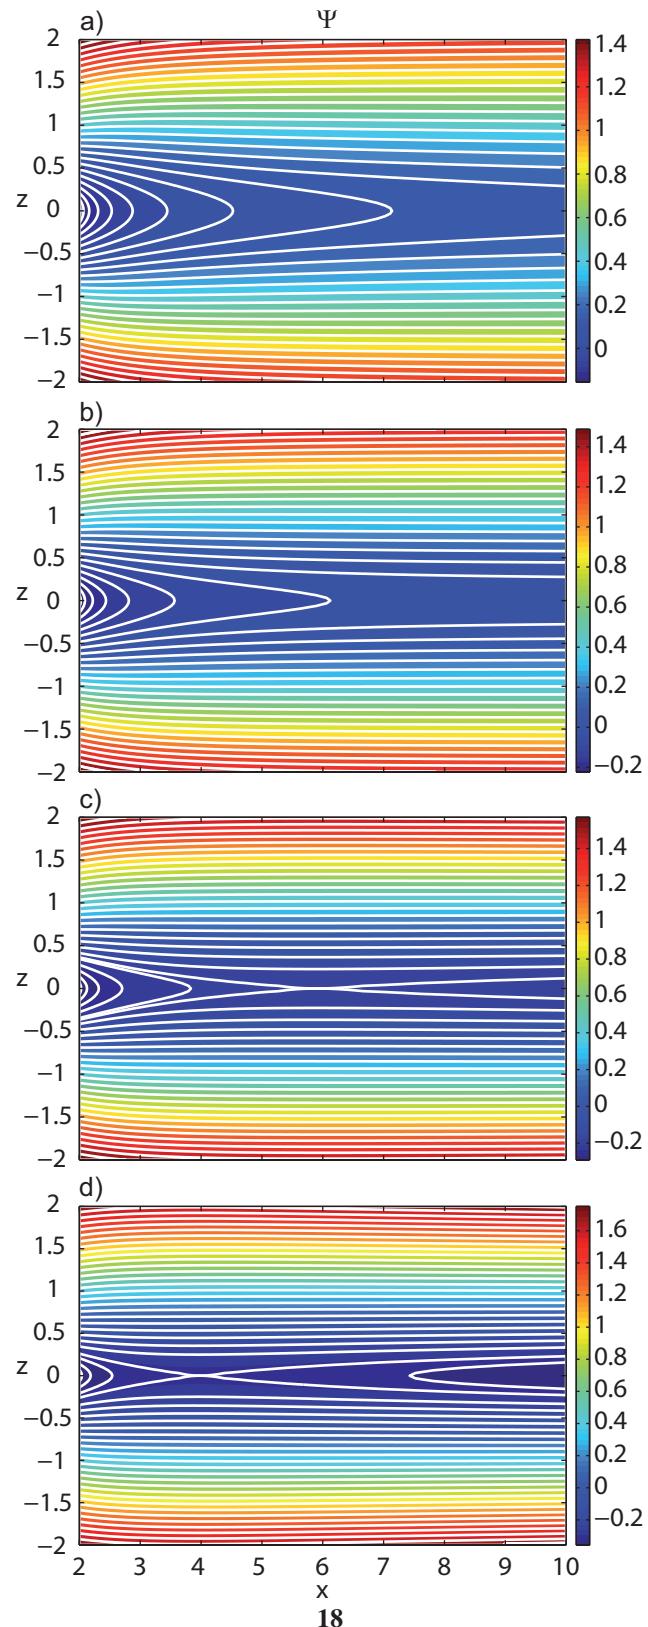

Figure 7. Magnetic configurations by analytical model (11–16) for $a = 0$, $b_0 = 1$, $\varphi = 0$, $f = 0$, $k = 1$, and $n = \{0.95, 1, 1.05, 1.1\}$ are shown on panels {a, b, c, d}, respectively. Panel b) shows the original Kan solution.

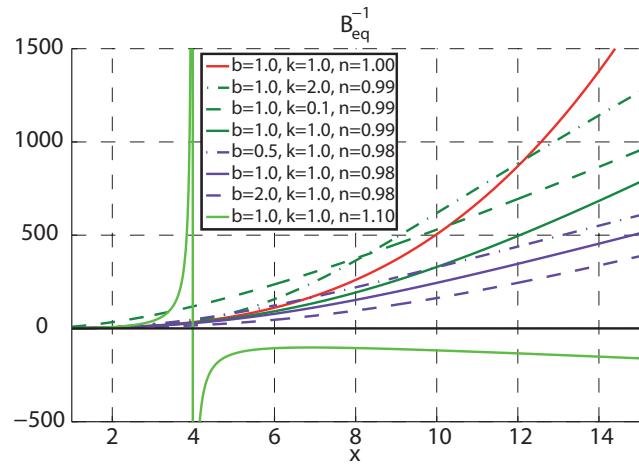

Figure 8. Profiles $1/B_z(x, 0)$ for symmetric Kan-like CS $\{a = 0, \varphi = 0, f = 0\}$ by analytical model (11–16) are shown for: $\{b_0 = 1, k = 1, n = 1\}$ (red), $\{b_0 = 1, k = 2, n = 0.99\}$ (dark-green dash-dotted), $\{b_0 = 1, k = 0.1, n = 0.99\}$ (dark-green dashed), $\{b_0 = 1, k = 1, n = 0.99\}$ (dark-green solid), $\{b_0 = 0.5, k = 1, n = 0.98\}$ (violet dash-dotted), $\{b_0 = 1, k = 1, n = 0.98\}$ (violet solid), $\{b_0 = 2, k = 1, n = 0.98\}$ (violet dashed), $\{b_0 = 1, k = 1, n = 1.1\}$ (light-green). Red curve shows the original Kan solution.
