**Abstract:** As a new detection method of three-dimensional water vapor, the ground-based water vapor tomography technique using Global Navigation Satellite Systems (GNSS) observations can obtain the high spatial and temporal distribution information of tropospheric water vapor. Since the troposphere tomography was proposed, most previous studies belong to the pixel-based method, dividing the interest area into three-dimensional voxels of which the water vapor density of each voxel center is taken as the average water vapor density. However, the abovementioned method can only find the water vapor density value of the center of each voxel, which is unable to express the continuous change of water vapor in space and destroys the spatial continuity of water vapor variation. Moreover, when using the pixel-based method, too many voxels are needed to express the water vapor density, which leads to the problem of too many coefficients to be estimated. After analyzing the limitations of the traditional pixel-based troposphere tomography technique, this paper proposes a new GNSS tropospheric water vapor tomography model combining the pixel-based and function-based models for the first time. The tomographic experiences were validated using the data from 12 stations from the Hong Kong Satellite Positioning Reference Station Network (SatRef) collected between 25 March and 25 April 2014. The comparison between tomographic results and the European Centre for Medium-Range Weather Forecasts (ECMWF) data is mainly used to analyze the accuracy of the new model proposed in this paper under different conditions, for showing that this new model is superior to the traditional pixel-based model in terms of root-mean-square error (RMSE) and bias. The new model has more advantages than the traditional pixel-based model on the RMSE, especially when obtaining the water vapor in voxels without the penetration of GNSS rays, which is improved by 5.88%. This model also solves the problem with more ease and convenience in expression.

**Keywords:** GNSS; water vapor tomography; functional-based technique; ECMWF

## 1. Introduction

The distribution of water vapor is complex and highly variable, and water vapor, as the most active key component of the atmosphere, is indeed hard to describe accurately (Rocken et al., 1997). An in-depth understanding of temporal and spatial variation of water vapor plays an important role in improving the accuracy of weather forecasting and early warning of disastrous weather (Weckwerth et al., 2004).

GNSS water vapor monitoring techniques can not only acquire the two-dimensional spatial and temporal distribution of water vapor in the horizontal direction (Bevis et al, 1994; Emardson et al, 1998; Baltink et al, 2002; Bock et al, 2005) but can also use a three-dimensional tomography method to reconstruct the vertical structure of water vapor at high temporal-spatial resolution (Flores et al, 2000; Seko et al, 2000; Macdonald et al, 2002).

Braun et al. (1999) first proposed the concept of reconstructing the tropospheric water vapor structure using 20 GPS stations in a regional observational network. Flores et al. (2000) first presented a method of recovering slant wet delay (SWD) and obtained the water vapor density using the observation of SWD by singular value decomposition (SVD) combined with a least square method. In the same year, Hirahara (2000) used different methods to conduct tropospheric tomography experiments, which also confirmed the feasibility of obtaining three-dimensional water vapor fields using GPS technology. Since then, many scholars have studied GNSS troposphere tomography techniques and completed many research experiments (Rohm et al, 2014; Yao Y B et al., 2016a, 2016b, 2016c).

Regarding the tropospheric tomographic model solution and algorithm improvement, Hirahara et al. (2000) conducted a four-dimensional tropospheric wet refractivity retrieval of the GPS network from Shigaraki and solved the observation equations using the damping least-squares method, which is commonly used in seismic tomography. Braun et al. (2003, 2004) overcame the sensitivity problem in tomographic results by using the extended sequential filtering method. Perler et al. (2011) presented a new parameterization method for water vapor retrieval. The measured and simulated data proved that this method can obtain better tomographic solution results of water vapor. Adavi and Mashhadi (2015) used virtual reference station observations to retrieve the three-dimension distribution of atmospheric water vapor information in northwestern Iran. The results showed that this method can effectively improve the rank deficit problem of the tomographic normal equation. Nilsson and Gradinarsky (2006) obtained the tropospheric tomographic results directly from the original GNSS phase observations combined with the Kalman filter method. Rohm and Bosy (2009) used the Moore-Penrose pseudo-inverse of variance-covariance to solve the linear equations and emphasized the ill-posed tomography equation. Zhao and Yao (2016) also obtained good results by using the optimal grid-making method for water vapor tomography. In the meantime, a method of using the side-penetrating signals for tomography was proposed to improve the effect of GNSS ray utilization rate.

Although GNSS tomography techniques have been developed for more than two decades, it has been challenging to enhance the water vapor quality and the stability of the solution results through the multi-system and multi-source data combination method and improve the tomographic model solution and algorithm. However, in the previous studies, most water vapor tomography methods belong to the pixel-based model, which means that the three-dimensional meshes of the study area were used, and the water vapor density at the center of each voxel was taken as the average water vapor density of the whole voxel. However, only could find the water vapor density value of the center of each voxel, the pixel-based tomography is unable to continuously express the change of water vapor in space and also breaks the spatial continuity of the water vapor. Since the three-dimensional water vapor density is stored through the voxels, a large amount of voxel information (spatial position, water vapor density within the voxel, etc.) is required

when describing the spatial water vapor density distribution, which is inconvenient for later use (Yao Y, Chen P, 2013). What's more, though some constraints could be put on apriori models in order to overcome the ill-posed problem in pixel-based tomography, some errors due to empirical constraints would be added artificially. Thus, this paper analyzes the limitations of traditional pixel-based tropospheric water vapor tomography and proposes a new tropospheric tomography model combining the pixel-based and function-based models. This method combines the advantages of both the function-based method in facilitating the continuity of water vapor expression in spatial-temporal distribution and the pixel-based method ease in solving to retrieve the three-dimensional water vapor distribution in the interest region. The experimental results show that the accuracy of the new combinatorial model is improved, and the new model has more advantages when obtaining the water vapor in voxels without GNSS rays penetrating. Under strong rainfall weather conditions, the tomographic results of the new combinatorial model are more stable and reliable.

## 2. A tropospheric tomography model combining the pixel-based and function-based models

### 2.1. Establishment of the traditional troposphere tomography model

#### 2.1.1. Retrieval of SWV

For tropospheric tomography, the most important observation is the slant water vapor (SWV), which is related to the water vapor density and can be defined by

$$SWV = \int_s \rho_v ds \quad (1)$$

where  $s$  represents the path of the satellite signal ray, and  $\rho_v$  is the water vapor density (units: g/m<sup>3</sup>).

SWV can be obtained by the following method:

$$SWV = \frac{10^6}{R_w[(k_3/T_m) + k_2]} \cdot SWD \quad (2)$$

where  $k_2=16.48 \text{ K hPa}^{-1}$ ,  $k_3=3.776 \times 10^5 \text{ K}^2 \text{ hPa}^{-1}$ , and  $R_w=461(\text{J kg}^{-1} \text{ K}^{-1})$ , which represent the specific

gas constants for water vapor.  $T_m$  is the weighted mean tropospheric temperature, calculated from an empirical equation proposed by Liu et al. (2001) using the meteorological measurements. SWD is the slant wet delay, which may be given as

$$SWD_{elv,\varphi} = m_{wet}(elv) \times ZWD + m_{wet}(elv) \times \cot(elv) \times (G_{NS}^w \times \cos \varphi + G_{WE}^w \times \sin \varphi) + R \quad (3)$$

where  $elv$  is the satellite elevation,  $\varphi$  is the azimuth,  $m_{wet}$  is the wet mapping function,  $G_{NS}^w$  and  $G_{WE}^w$  are the wet delay gradient parameters in the east–west and north–south directions, respectively.  $R$  refers to the unmodeled zero difference residuals that may involve unmodeled influence on three-dimensional spatial water vapor distribution, which can make up for the lack of tropospheric anisotropy using only the gradient term (Bi et al. 2006). Since the GAMIT software only provide the double difference residuals, the zero difference residuals in this paper are obtained from the double difference residuals according to the method proposed by Alber et al. (2000). ZWD is the zenith wet delay, which is extracted from the zenith tropospheric delay (ZTD) by separating the zenith hydrostatic delay (ZHD) using equation  $ZWD=ZTD-ZHD$ . ZHD can be calculated precisely using surface pressure based on the Saastamoinen model (Saastamoinen 1972):

$$ZHD = \frac{0.002277 \times P_s}{1 - 0.00266 \times \cos(2\varphi) - 0.00028 \times H} \quad (4)$$

where  $P_s$  is the surface pressure (unit: hPa),  $\varphi$  is the latitude of the station, and  $H$  is the geodetic height (unit: km). The unit of ZHD is meter.

Since the SWV is obtained, the tomographic area can be discretized into a number of voxels, in which water vapor density is a constant during a given period of time. Therefore, a linear equation relating SWV and water vapor density can be established as follows (Chen and Liu 2014):

$$SWV^{\rho} = \sum_{ijk} (D_{ijk}^{\rho} \cdot \rho_{ijk}) \quad (5)$$

where  $SWV^{\rho}$  is the slant water vapor of  $\rho$ th signal path (unit: mm).  $i, j$ , and  $k$  are the positions of discrete tomographic voxels in the longitudinal, latitudinal and vertical directions, respectively.  $D_{ijk}^{\rho}$  is the distance of the  $\rho$ th signal in voxel  $(i, j, k)$  (unit: km).  $\rho_{ijk}$  is the water vapor density in a given voxel  $(i, j, k)$  (unit:  $\text{g/m}^3$ ). A matrix form of this observation equation can be rewritten as follows (Flores et al. 2000; Chen and Liu 2014):

$$y_{m \times 1} = A_{m \times n} \cdot \rho_{n \times 1} \quad (6)$$

where  $m$  is the number of total SWVs, and  $n$  is the number of voxels in the tomographic area.  $y$  is the observed value here as the SWV, which penetrates the whole interest area,  $A$  is the coefficient matrix of the signal transit distances through the voxels, and  $\rho$  is the column vector of the unknown water vapor density.

#### 2.1.2. Constraint equations of the Tomography Modeling

Solving for the unknown water vapor density in Eq. (6) is actually an inversion algorithm issue as the design matrix  $A$  is a large sparse matrix, whose normal equation is singular, leading to numerical problems when using a direct inversion method (Bender et al., 2011a). To overcome this rank deficiency problem, constraint equations are often introduced to the tomography equation (Flores et al., 2000; Troller et al., 2002; Rohm and Bosy, 2009; Bender et al., 2011a). In our study, horizontal constraint equation is imposed by the Gauss-weighted functional method (Guo et al, 2016) and the vertical constraint equation is imposed by the functional relationship of the exponential distribution (Cao Y, 2012), respectively. The final tomography model is then obtained as

$$\begin{pmatrix} A_{m \times n} \\ H_{m \times n} \\ V_{m \times n} \end{pmatrix} \cdot \rho_{n \times 1} = \begin{pmatrix} y_{m \times n} \\ 0_{m \times n} \\ 0_{m \times n} \end{pmatrix} \quad (7)$$

where  $H$  and  $V$  are the coefficient matrices of horizontal and vertical constraints, respectively. In order to obtain the inverse matrix shown in Eq. (7), singular value decomposition is used in this paper (Flores et al., 2000).

#### 2.2. Tropospheric tomography model combining the pixel-based and function-based models

The combinatorial tomographic model proposed in this paper can take full advantage of the function-

based model in facilitating the continuity of water vapor expression in spatial-temporal distribution and the pixel-based model in calculating water vapor density conveniently. The combinatorial tomographic model begins to obtain the water vapor density saved as the observation value from voxels penetrated by GNSS rays using the traditional pixel-based tomographic model and then obtains the optimal polynomial function of each layer through adaptive training. Using the optimal polynomial fitting function of each layer with known coefficients, the water vapor densities can finally be calculated in any tomographic region by given the latitude, longitude and the altitude. Specific steps are as follows:

First, use the traditional pixel-based tomography model to obtain the initial water vapor density from voxels penetrated by GNSS rays in the tomographic region of each layer as the observed values for obtaining the optimal polynomial function coefficient of each layer.

Second, normalize the coordinates of each voxel center in the tomographic area. Since the polynomial fitting of the water vapor at each tomographic layer is in essence establishing the relationship between the latitude as well as the longitude of the tomographic region and the water vapor density. The general expression is:

$$V_d = a_0 + a_1B + a_2L + a_3BL + a_4B^2 + a_5L^2 + a_6B^2L \cdots \quad (8)$$

where  $B$  is the latitude,  $L$  is the longitude, and  $V_d$  represents the water vapor density. Polynomial coefficients such as  $a_i$  are obtained via the least squares method. In the process of solving, because the numerical values of latitude and longitude are not small, the magnitude of multiple power may be larger than  $10^4$ , which will lead to the ill-posed problem of the design matrix in the inversion process and affect the reliability of the estimated coefficients. To ensure that the design matrix constructed will be relatively stable in the inversion process, the latitude and longitude coordinates  $B$  and  $L$  need to be normalized. The specific methods are as follows:

$$\begin{aligned} B^* &= \frac{B - \mu_B}{\sigma_B} \\ L^* &= \frac{L - \mu_L}{\sigma_L} \end{aligned} \quad (9)$$

where  $B^*$  and  $L^*$  are the normalized latitude and longitude, respectively, and  $B$  and  $L$  are the latitude and longitude in the initial region range.  $\mu$  is the average value of latitude or longitude, and  $\sigma$  is the standard deviation of latitude or longitude.

Third, build the function-based model part of the new combinatorial tomographic method, through adaptive training to determine the optimal polynomial function of each layer.

- First, based on the size of the selected tomographic region, determine the highest polynomial fit order. In this paper, the highest polynomial fit order chosen as 5 turns out to be generally sufficient.
- Through obtaining the water vapor density from voxels penetrated by GNSS signal rays in the tomographic region of each layer as the input value and constantly trying out new polynomial functions, the optimal polynomial function of each layer is obtained by simulated training.

During the processes of training and comparison, the number of voxels penetrated by GNSS

rays initially should be paid attention to since the number of estimated coefficients need to be less than that of the voxels penetrated by GNSS rays in each layer. Under this premise, the over-fitting problem should also be avoided, otherwise it would be counterproductive.

- Finally, after comparison of the training results of multi-group polynomial functions at different levels, the polynomial function of the minimum RMSE value after the post-fitting layer and fitting of the ECMWF results is the best fit equation for this layer. Each layer could have the individual optimal polynomial function in general.

Fourth, after finding the optimal polynomial function of each layer in different heights, use the latitude, longitude and altitude information into the function to obtain the three-dimensional water vapor distribution of any position in the tomographic region. The three-dimensional water vapor field in the tomographic zone can be described by broadcasting the estimated coefficients of the optimal polynomial function of each layer.

### 2.3. The optimal polynomial selection based on adaptive training

Since the polynomial form can better reflect the continuity of water vapor and has the advantage of high-efficiency computing as well as easy expression, this paper chooses the polynomial form as the function-based model. The selection process of the optimal polynomial function based on adaptive training is as follows:

First, to construct a polynomial equations training library, which contains a wide variety of polynomial function forms of latitude and longitude as independent variables, use the water vapor density in the voxels as the dependent variable. After many experiments, the maximum power of latitude and longitude found as 5 is sufficient to describe the water vapor changes. Therefore, the maximum power of the function-based part is adopted as 5 in the training library.

Second, according to the water vapor density observations from the voxels penetrated by the GNSS signals at each level, the form of the candidate polynomial function of each layer is automatically determined from the polynomial function training library to ensure that the number of observations at all levels is always greater than the number of estimated coefficients of the candidate polynomials.

Third, calculate the water vapor variation index (WVVI) of each layer in both east-west and south-north directions with the traditional tropospheric tomographic results as shown in Eq. (10).

$$WVVI = \frac{\overline{wv}_{EW}}{\overline{wv}_{NS}} \quad (10)$$

Where  $wv_{EW}$  and  $wv_{NS}$  are the water vapor density in east-west and south-north direction, separately.

The WVVI, a changing rate indicator of water vapor density in a given direction, is obtained by calculating the overall average change rate of water vapor density in a given direction within each adjacent voxel. According to the water vapor variation index of each layer in the east-west and north-south direction, it can be determined whether water vapor exists mainly in the east-west distribution or the north-south distribution. As an aid, WVVI can choose the main body of the alternative polynomial function with higher order term of longitude or latitude for the subsequent accuracy comparison in order to efficiently and quickly find the optimal polynomial function of each layer. If the water vapor density of a layer indicates a horizontal gradient of east-west distribution, the polynomial function with higher-order term of longitude should be given the priority. It suggests that when the water vapor shows an east-west gradient distribution there is a better correlation between longitude and water vapor variation, furthermore the high-order term in longitude can better reflect the nuanced water vapor variation. A simple example of the polynomial

function with a higher-order term in longitude is shown in Eq. (11):

$$V_d = a_0 + a_1B + a_2L + a_3BL + a_4L^2 + a_5BL^2 + a_6L^3 \quad (11)$$

Otherwise, when the water vapor density of a layer indicates a horizontal gradient of north-west distribution, the polynomial function with higher-order term of latitude should be given the priority. A simple example is shown in Eq. (12):

$$V_d = a_0 + a_1B + a_2L + a_3BL + a_4B^2 + a_5B^2L + a_6B^3 \quad (12)$$

While the distribution regularities of water vapor density gradient are not clear and obvious, the polynomial function with the same order of latitude and longitude can be considered as the example shown in Eq. (13):

$$V_d = a_0 + a_1B + a_2L + a_3BL + a_4B^2 + a_5L^2 \quad (13)$$

Fourth, the candidate polynomials of all levels screened by the WVVI gradient auxiliary information are used as the next comparative polynomials, and the required estimated coefficients of the comparative polynomial are solved according to the principle of least squares through Eq. (14) and automatically recorded into the coefficients data set.  $M$  is the matrix of longitude and latitude, and the vector  $x$  comprises the unknown coefficients of the comparative polynomial functions as shown in Eq. (15).

$$V_d = Mx \quad (14)$$

$$x = \begin{bmatrix} a_0 \\ a_1 \\ \vdots \\ a_n \end{bmatrix} \quad (15)$$

Fifth, through the comparative polynomials with the estimated coefficients in each layer, the whole-voxel water vapor fitting of each layer is automatically fit with the information of the latitude and longitude. In order to obtain the RMSE, the fitting result would be compared with the ECMWF water vapor density of each layer in this period. The results are then saved to the accuracy data sets of each layer. The comparative polynomials with the estimated coefficients are constantly selected to train the fitting of the layered water vapor density and then compared with the water vapor density of ECMWF at each layer. Thus, large accuracy data sets of RMSE can be obtained, where the smallest RMSE value of the comparative polynomial form can be chosen, and then the optimal polynomial of each layer could come into being. It is noteworthy that the optimal polynomial of each layer might be different. With the optimal polynomial of each layer, the three-dimensional water vapor density in the tomographic region can be expressed conveniently and continuously by transmitting the estimated coefficients information.

### 3. Experiment

#### 3.1. Experimental description and data-processing strategy

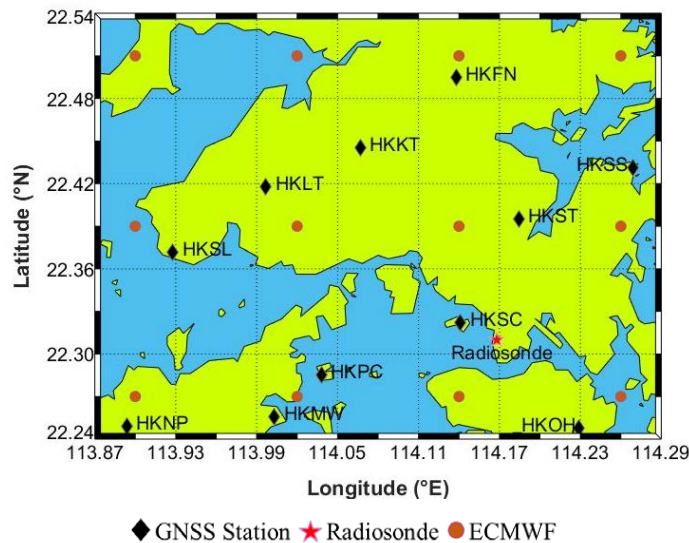

To study whether the accuracy and stability of the results of the tropospheric tomography model combining the pixel-based and function-based models proposed in this paper are better than the traditional pixel-based tropospheric tomography model, the following experiment is designed.

Tomographic data is obtained from the SatRef Network for Hong Kong from 25 March 2014 to 25 April 2014. Two epochs are taken each day (0:00 and 12:00). The corresponding meteorological data is also used to calculate the PWV. The tomographic area ranges between latitude 22.23°N to 22.53°N and

longitude 113.87°E to 114.29°E. Taking the mean sea level as the height of base level, the vertical resolution is 0.8 km, and total grid number is  $5 \times 7 \times 13$ . In the selected area, a total of 11 GNSS stations and 1 radiosonde station are selected, and the ECMWF grid data are extracted twice daily at UTC 00:00 and 12:00 from 25 March 2014 to 25 April 2014 (grid resolution of  $0.125 \times 0.125$ ). See Fig. 1 for details.

**Figure 1: The GNSS (11 black rhombuses) and radiosonde (1 red star) stations and ECMWF comparative points (12 ochre circles) in Hong Kong. The grid lines display tomography grids.**

According to the official website of the Hong Kong Observatory (<http://www.weather.gov.hk/contentc.htm>) for the weather review, Hong Kong had a total of 15 days of rainy weather during 25 March 2014 to 25 April 2014, as shown in Table 1.

**Table 1.** Rainfall information for March and April 2014

Date	Rainfall situation
3.29	Thunderstorms turn to heavy rain
3.30	Thunderstorms turn to heavy rain
3.31	Thunderstorms turn to heavy rain
4.1	Shower accompanied by wind, thunderstorms
4.2	Showers, reports of hail in some areas
4.3	Showers, some parts of the rain are quite large
4.6	Cloudy shower, low temperature
4.7	Heavy shower, low temperature
4.8	Showers, low temperatures
4.14	Shower
4.21	Cloudy turns to the shower
4.22	Showers and foggy
4.23	Showers turn to the rain
4.24	Showers turn to the cloudy
4.25	Cloudy turns to the rain

In this paper, GAMIT (v10.50) (Herring et al., 2010) software was used for processing the GPS

observations based on the double-differenced model at a sampling interval of 30 s, and the global mapping function was adopted. The zenith total delay (ZTD) and wet horizontal gradient intervals were estimated at 0.5 h and 2 h, respectively. Based on the surface pressure obtained from observed meteorological parameters, the ZHD could be obtained by the Saastamoinen model, and ZWD was isolated from ZHD. Via GMF projection, the SWD could be obtained by transforming the observed SWV.

### 3.2. Experimental introduction and program comparison

The RMSE and bias of the combinatorial tomographic model residuals were calculated by subtracting the ECMWF water vapor density from the water vapor density of the GNSS tropospheric tomography model combining the pixel-based and function-based models (hereinafter referred to as combinatorial tomographic model). In a similar way, the RMSE and bias of the traditional tomographic model residuals can also be obtained from the difference between the ECMWF water vapor density and the three-dimensional water vapor density obtained by the traditional ground-based GNSS pixel-based troposphere water vapor tomography model (hereinafter referred to as the traditional tomographic model).

In the period of data processing, the situation can be compared on a case-by-case basis to comprehensively evaluate the accuracy of the combinatorial tomographic model from various views. In this paper, 6 case scenarios are investigated, comprising the spatial distribution scenario, the everyday distribution scenario, the rainy situation and the non-rainy case. Moreover the residuals of water vapor density in voxels with and without penetrating GNSS rays are inspected. The definitions of 6 case scenarios abovementioned are as follows:

The spatial distribution scenario is investigated by obtaining the RMSE and bias of the residuals from all ECMWF comparative points at all time intervals as well as the accuracy of each layer in thirteen layers of the tomographic area is calculated.

The everyday distribution situation is found by obtaining the RMSE and bias of the residuals from all ECMWF comparative points in two epochs each day, and the overall accuracy of 32 days between 25 March and 25 April, 2014 was calculated.

The rainy case is based on the distribution of 15 days of rainy days between 25 March and 25 April, 2014, as referred to in Table 1, in which the RMSE and bias of the residuals are obtained from all ECMWF comparative points in all the epochs in rainy days for further accuracy analysis. Similarly, the non-rainy situation is found with an accuracy analysis of the non-rainy days.

The situation of residuals of water vapor density in voxels without GNSS rays penetration is found by obtaining the RMSE and bias of the residuals from ECMWF comparative points without rays passing through in all the epochs each day. Conversely, the situation with GNSS rays penetration is found by obtaining the RMSE and bias of the residuals from ECMWF comparative points with rays passing through in all the epochs each day.

According to the above classifications, the accuracy of the combinatorial tomographic model residuals and the traditional tomographic model residuals were calculated, and the accuracy of the new model was compared with the traditional model to determine which model is better.

## 4. Interpretation of the results

### 4.1. Accuracy information of the spatial distribution situation

To verify whether the accuracy of the combinatorial tomographic model is better than that of the traditional tomographic model, the layered RMSE and bias of the residuals from all ECMWF comparative points at all time intervals between the tomography (using both the optimal polynomial function of each layer and the traditional way) and the ECMWF results are obtained and shown in Table 2, and the calculation of RMSE improvement percentage involved in the following tables is shown in Eq. (16).

$$\Delta RMS\% = (RMS_{trad} - RMS_{comb}) / RMS_{trad} \cdot 100\% \quad (16)$$

where  $RMSE_{comb}$  is the RMSE value of the residuals calculated from the combinatorial tomographic model, and  $RMSE_{trad}$  is the RMSE value of the residual obtained from the traditional tomographic model.

Table 2 shows that RMSE and bias values obtained by the combinatorial tomographic model are smaller than those of the traditional tomographic model, and the RMSE improvement percentage is positive, which indicates that the combinatorial tomographic model has a higher accuracy than the traditional tomographic model overall. Moreover, the RMSE improvement percentage is appreciable in the upper region because the value of water vapor density in high altitude is very small, even the small changes in the upper region could result in a large percentage change. In addition, the bias and RMSE in the bottom from Table 2 are not as good as those of the other higher layers, regardless of which model is used. These results could be mainly ascribed to a certain system deviation between the comparison data of ECMWF and the GNSS tomographic data. Besides, the observations and the number of redundant observations are insufficient due to less rays passing through the voxels in the bottom and then result in low accuracy. What's more, the water vapor content in the bottom region too abundant and changeable to be generally describe accurately. The above reasons lead to large bias and RMSE in the bottom tropospheric area.

**Table 2.** Statistics of two models' tomography accuracy with respect to ECMWF data in the spatial distribution scenario in 2014 (Unit: g/m<sup>3</sup>)

Layer	bias		RMSE		RMS
	Traditional model	Combinatorial model	Traditional model	Combinatorial model	Improvement Percentage
1	-7.81	-7.65	8.17	8.00	2.06%
2	-3.52	-3.42	3.95	3.83	3.14%
3	-0.90	-0.80	1.66	1.60	4.05%
4	0.72	0.61	1.39	1.36	2.00%
5	1.62	1.58	1.87	1.83	2.28%
6	1.95	1.77	2.10	2.09	0.39%
7	1.98	1.90	2.25	2.20	2.07%
8	1.76	1.68	2.15	2.10	2.32%
9	1.62	1.60	2.06	2.04	1.10%
10	1.34	1.11	1.85	1.47	20.68%
11	1.04	0.87	1.60	1.25	21.75%
12	0.74	0.61	1.26	0.96	23.67%
13	0.44	0.38	0.71	0.58	18.36%

#### 4.2. The accuracy information of the everyday distribution situation

To determine whether the accuracy of the combinatorial tomographic model is better than that of the traditional tomographic model on the everyday time scale, the RMSE improvement percentage is obtained from all ECMWF comparative points (a total of 12) at two epochs each day using both the optimal polynomial function of each layer and the traditional method. Figure 2 shows that the percentage of RMSE improvement per day is practically positive, and the percentage of April 11th can even approach 12%, indicating that the improvement seems to be appreciable. This improvement shows that the accuracy of the

combinatorial tomographic model is mostly superior to that of the traditional tomographic model in everyday distribution; however, on April 7, April 9 and April 15, the RMSE improvement percentage is negative. This might be due to the heavy showers bringing rapid water vapor change from April 7 to April 8 and on April 14, which is difficult to fit the polynomial function well with the unstable water vapor. However, since negative percentages do not exceed -1%, the accuracy of these four days calculated by the combinatorial tomographic model could be considered basically equivalent to that of the traditional tomographic model.

**Figure 2: Everyday Distribution Statistics of Daily RMSE Improvement Percentage between 25 March and 25 April, 2014.**

In addition, the overall RMSE and bias of the residuals are obtained from the ECMWF comparative points (a total of 12) in two epochs under the entire everyday distribution situation. The statistical results are shown in Table 3 below.

**Table 3.** Statistics of two models' tomography accuracy with respect to ECMWF data in the everyday distribution scenario in 2014 (Unit: g/m<sup>3</sup>)

Statistics type	Traditional model	Combinatorial model	RMS improvement percentage
RMS	2.97	2.87	3.44%
bias	0.07	0.02	

Table 3 shows that the RMSE obtained by the combinatorial model is smaller by 3.44% compared to the traditional one. The combinatorial model bias more closes to zero, indicating that the combinatorial tomographic model has better stability and less systematic deviation from the comparative data. Taking the extreme weather conditions such as the heavy rainfall during the period into account, the accuracy of the combinatorial tomographic model seems to be higher in bad weather situations to a certain extent. Compared with the traditional tomographic model, the new model can obtain a certain improvement in the tomographic results of water vapor density.

**4.3. The accuracy information of rainy and non-rainy situations**

To further analyze the reliability of the combinatorial tomographic model compared with the traditional tomographic model in different weather conditions, according to the distribution of rainy days in Table 1, all the rainy days data and non-rainy days data are used separately for tomography to obtain the

RMSE and bias of the residuals under corresponding weather conditions. The number of matching points is still 12 (see Fig. 1). The overall statistical results are shown in Table 4.

**Table 4.** Statistics of two models' tomography accuracy with respect to ECMWF data in the rainy situation and the non-rainy case in 2014 (Unit: g/m<sup>3</sup>)

(a) The overall rainy situation statistics			
Statistics type	Traditional model	Combinatorial model	RMS improvement percentage
RMS	3.05	2.94	3.68%
bias	0.05	-0.01	
(b) The overall non-rainy situation statistics			
Statistics type	Traditional model	Combinatorial model	RMS improvement percentage
RMS	2.89	2.80	3.21%
bias	0.10	0.04	

Table 4 (a) shows that the RMSE and bias of the residuals calculated by the combinatorial tomographic model are better than those of the traditional tomographic model using rainy day data. The RMSE of the combinatorial tomographic model is 3.68% higher than the traditional model, indicating the accuracy of the new model is superior. The combinatorial model bias closes more to zero than the traditional one, which means the new model has an increase in stability and a reduction in the system error. Using non-rainy day data, the RMSE and bias of the residuals calculated by the combinatorial tomographic model are also better than those of the traditional tomographic model, see Table 4 (b). The RMSE improvement percentage is 3.21%, also indicating there is an improvement in the accuracy of the new model. Besides, the combinatorial model bias is more close to zero, making the system error weakened and the stability enhanced. According to the RMSE improvement percentage under the rainy and non-rainy situations, the RMS improvement percentage of rainy days is better than that of non-rainy days. This finding shows that the combinatorial tomographic model is more suitable for obtaining the tomographic results when severe water vapor changes occur.

#### 4.4. The accuracy information of voxels with and without GNSS rays penetrating situations

In the traditional pixel-based water vapor tomographic model, the water vapor density in the voxels without GNSS rays passing through depends on the accuracy of the water vapor density in the adjacent voxels with GNSS rays penetration. However, the combinatorial tomographic model uses an optimal polynomial as the function-based model for overall fitting to obtain the water vapor density in voxels without penetrating GNSS rays. To determine whether the function-based model part of the combinatorial method contributes better to the accuracy of water vapor density in voxels without GNSS rays passing through, the situations of voxels with and without GNSS rays penetration as described in section 3.2 were designed. After obtaining the RMSE and bias of the residuals using the combinatorial and traditional tomographic models separately under designed situations, the overall accuracy information of voxels with and without GNSS rays penetrating shows in Table 5.

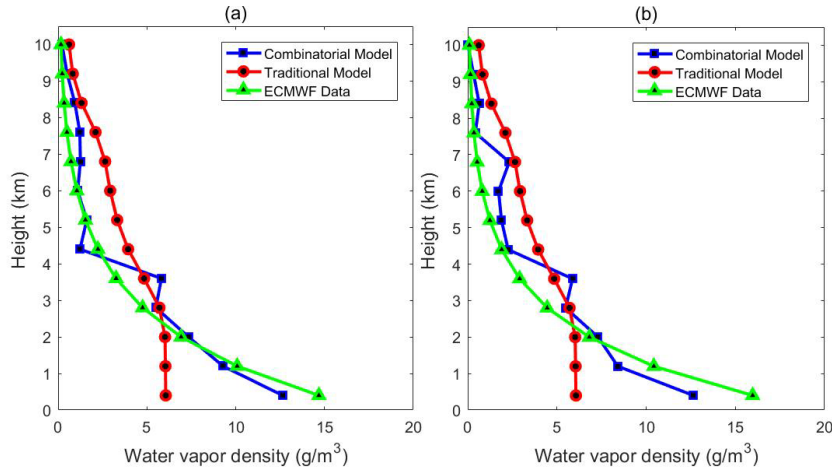

**Table 5.** Statistics of two models' tomography accuracy with respect to ECMWF data in the voxels with and without penetrating GNSS rays in 2014 (Unit:  $\text{g/m}^3$ )

(a) The overall situation statistics of voxels without rays penetrating			
Statistics type	Traditional model	Combinatorial model	RMS Improvement Percentage
RMS	3.40	3.20	5.88%
Bias	1.59	1.51	
(b) The overall situation statistics of voxels with rays penetrating			
Statistics type	Traditional model	Combinatorial model	RMS Improvement Percentage
RMS	3.27	3.24	1.00%
bias	1.70	1.65	

Table 5 (a) shows that the RMSE and bias of the residuals calculated by the combinatorial tomographic model are better than those of the traditional tomographic model in the situation of voxels without GNSS rays penetrating. Moreover the RMSE of combinatorial tomographic model is 5.88% better than that of the traditional tomographic model, and the bias decreased from 1.59 to 1.51. To a certain extent, this finding shows that the combinatorial tomographic model is more advantageous for obtaining the water vapor density from the voxels without GNSS rays penetrating, which is consistent with the initial hypothesis: the traditional tomographic model uses constraint equations in section 2.1.2, Eq. (7), which is unable to well represent the distribution of water vapor density from voxels without GNSS rays penetrating in the actual situation. However, the new proposed model uses the exact water vapor density from voxels with GNSS rays penetrating as the observation value for further fitting the water vapor density in voxels without GNSS rays penetrating, using optimal polynomial functions with estimated coefficients established by relatively actual water vapor distribution in each layer. In comparison, the combinatorial tomographic model can better reflect the layered actual situation of continuous water vapor changes, and the accuracy is naturally better. What's more, the RMSE and bias obtained by the combinatorial tomographic model are also superior to those of the traditional tomographic models using the classified data of voxels with GNSS rays penetrating, see Table 5 (b). The RMSE calculated by the new model is 1% higher than the traditional model, and the bias reduced by 4.73% from 1.7 to 1.65. In summary, whether it is calculated separately from data of voxels with or without GNSS rays penetrating, the results of the combinatorial tomographic model are superior to those of the traditional tomographic model to a certain extent, which could prove the advanced nature and reliability of the combinatorial tomography model.

In order to double-check if the combinatorial tomography model in the situation of voxels without GNSS rays passing through shows a better result in the vertical distribution of 3D water vapor density, the water vapor density profiles for different altitudes at individual times are given in Fig. 3. Two times (0:00 UTC 11 April 2014 and 12:00 UTC 11 April 2014) are chosen for they correspond to the maximum percentage of RMSE improvement during the experiment period of 32 days. Figure 3 shows that in the situation of voxels without GNSS rays penetration, the water vapor profile of combinatorial tomography model better matches that from ECMWF than the traditional tomographic model at both times, especially in the bottom layers, which implies that the water vapor density derived from the proposed model is superior to that of the traditional tomography model in the situation of voxels without penetrating GNSS rays.

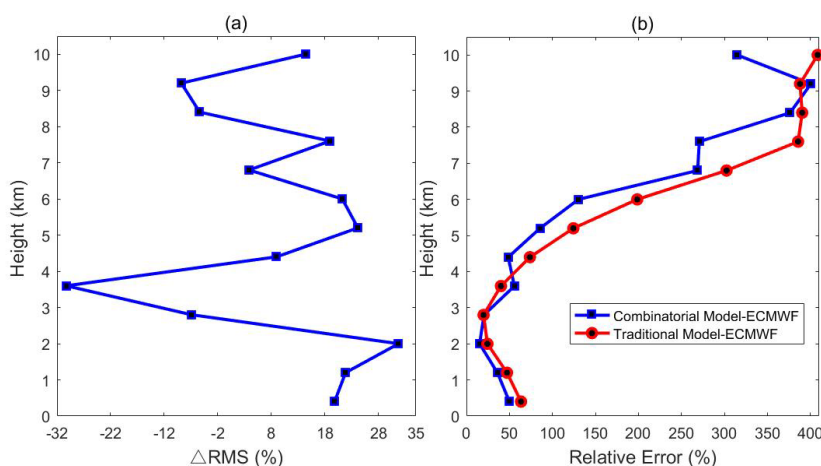

**Figure 3: Water vapor profiles derived from ECMWF and two models in the situation of voxels without penetrating GNSS rays, (a) and (b) are periods of 0:00 – 0:30 UTC 11 April 2014 and 12:00 – 12:30 11 April 2014, respectively.**

Furthermore, to compare directly the vertical accuracy of water vapor density derived from different altitudes in the situation of voxels without penetrating GNSS rays, the tomographic results (25 March 2014 to 25 April 2014) from two different tomography models are analyzed. Figure 4 shows the percentage of RMSE improvement and relative error change with altitudes. The percentage of RMSE improvement in Fig. 4 is defined as the same as Eq. (16), and the relative error is defined by using the Eq. (17).

$$RE = \frac{\rho - \rho_{ECMWF}}{\rho_{ECMWF}} \quad (17)$$

where RE is the relative error,  $\rho$  represents the water vapor density derived from the traditional or combinatorial tomography model, and  $\rho_{ECMWF}$  is the water vapor density derived from ECMWF grid data.

It can be observed in Fig. 4 that in the situation of voxels without GNSS rays penetration, the percentage of RMSE improvement is positive in lower layers while negative in some middle and upper layers, which could prove that the proposed model improves the accuracy of tomography results in most layers when there are seldom voxels with GNSS rays penetrating especially in the bottom layers. Due to the lack of GNSS observation data, the bottom accuracy of tomographic results is always low. In addition, Figure 4 shows in the situation of voxels without GNSS rays penetration, the relative error begins to decrease with the altitude and then increases above 3 km. When the altitude is higher, the relative error becomes larger, this is due to the small water vapor values of the upper layers, and just a very tiny difference could cause a large relative error between the models and ECMWF water vapor density data.

**Figure 4:** The percentage of RMSE improvement and relative error change with height in the situation of voxels without GNSS rays penetration (blue curve and red curve are derived from the differences between the profiles of the combinatorial tomography model, the traditional tomographic model and ECMWF grid data, separately for 64 epochs spanning from 25 March 2014 to 25 April 2014).

## 5. Conclusion

In this paper, a new tropospheric tomography model combining the pixel-based and function-based models has been proposed, which is much more concise and convenient in expression and use than the traditional pixel-based tomographic model. Only the optimal polynomial coefficients of each layer as the function-based part are required to describe the three-dimensional water vapor distribution in the tomographic region. By using the SatRef GNSS network observation data in Hong Kong between 25 March and 25 April, 2014, the RMSE and bias have been assessed in 6 scenarios. The situations include the spatial distribution situation and the everyday distribution situation, the rainy situation and the non-rainy situation, and the voxels with and without GNSS rays penetrating situations. The results demonstrate that regardless of the situation, the RMSE and bias of the new combinatorial tomographic model are better compared to the traditional tomographic model. Among these situations, when there are voxels without GNSS rays penetrating, the RMSE improvement percentage can be significantly increased up to 5.88%, which shows that the combinatorial tomographic model is more advantageous for obtaining the water vapor density from voxels without GNSS rays passing through. For the rainy situation, the bias improvement percentage can reach 76.18%, which shows that the proposed model is more stable in heavy rainfall. However, some shortcomings remain in the GNSS tropospheric combinatorial tomographic model. For example, when constructing the optimal polynomial of each layer, the polynomial is not only limited by the water vapor density quality in voxels with rays passing through calculated by the traditional pixel-based tomographic model, but it is also limited by the size of the tomographic area and the situation of dividing voxels. In the future, the purely function-based tomographic model of the troposphere should be further studied, which is free from the above limitations. It is expected that the tropospheric tomographic model will be more conveniently used and expressed when the polynomial coefficients could be obtained directly from SWVs.

**Acknowledgments:** The authors would like to thank ECMWF for providing access to the layered meteorological data. The Lands Department of HKSAR is also acknowledge for providing GPS data from the Hong Kong Satellite Positioning Reference Station Network (SatRef) and corresponding meteorological data.

**Conflicts of Interest:** The authors declare that they have no conflict of interest.
