Interactive comment on "Impact of magnetic storms on the global TEC distribution" *by* Donat V. Blagoveshchensky et al.

Anonymous Referee #2

Received and published: 30 March 2018

General Comments to the Authors:

The article is very interesting reporting significant findings. The results are of high quality and mostly well presented. However, there are some issues that need to be dealt with. These include the moving front, the inspection of actual TEC maps published by Madrigal Database, and the preferable usage of 1-min SYM-H index instead of the hourly Dst index. Based on the actual TEC maps, the description of moving front during the 31 December 2015 storm needs to be corrected.

Specific Comments:

Page (P) 3 Line (L) 7: "object", "subject" sounds better

P4 L10-15: As storms create sudden ionospheric and TEC changes, it

Discussion paper

would be better to use actual TEC values provided by the Madrigal Database (http://cedar.openmadrigal.org/) than averaged 2-hourly GIM TEC values for storm studies. They use predictions to fill the data gaps and averaging over 2 hours that smooths out the storm induced sudden TEC variations.

P4 L25: The 1-min SYM-H index provided by the OMNI database (https://cdaweb.gsfc.nasa.gov/cdaweb/istp_public/) and by the World Data Center for Geomagnetism, Kyoto (http://wdc.kugi.kyoto-u.ac.jp/aeasy/index.html) would be better than the 1-hour Dst index because of its higher time resolution. This higher resolution makes research more accurate. For example, the minimum SYM-H for the last storm, superstorm, was -234 nT reached at 2247 UT and not -223 nT at 2300 UT given by the hourly Dst index.

In Figure 3, the individual plots are too small and their labels are very hard to read.

P6 L30: I do not agree with the concept of disturbance front moving towards the equator applied to the 31 December 2015 storm. These TEC maps shown (see attached PDF) are from the Madrigal Database. The left column is for the end of 31 December 2015, the right column is for 3 hours latter. As the TEC maps show in the left column, there was a high TEC region in the American longitude sector and over the Pacific Ocean with large data gaps where GIM fills the gap with predicted values. But in these TEC maps, we can see actual TEC values and they show that these high TECs remained simultaneously at equatorial, low- and mid-latitudes. There was a peak over the magnetic equator, which is possibly the nighttime equatorial peak (or anomaly) implying that the vertical equatorial ExB drift was downward directed and drove a reverse plasma fountain that created this equatorial peak. However, at the same time, there were equally high TECs at mid-latitudes over the ocean. According to the velocity value given by the authors, the travelling time is 3 hours between +/- 40 GLAT and the equator. The right column shows the TEC maps 3 hours latter. As the storm progressed, we can see in the American sector the much lower TECs and the peaks of the Equatorial Ionization Anomaly (EIA) indicating that the vertical equatorial ExB drift was upward

directed and drove a forward plasma fountain that created this EIA. The moving front section should be re-written and explained better because it is not supported by the actual TEC maps: there were equally high values at mid- and low-latitudes and over the equator (see left column). In terms of moving peaks, these actual TEC maps show that the equatorial peak turned into an EIA, characterized by a northern and a southern crest, as the vertical equatorial ExB drift flipped from downward to upward . So, the peak TEC moved from the equator to both hemispheres' lower latitudes and not from mid-latitude towards the equator as the authors claim.

P11 L25: As suggested, the authors should study the TEC maps of Madrigal Database regarding the moving front and make the necessary corrections.

P13 L10: Other data types (Dst/SYM-H, GOES) should be acknowledged as well.
