13 **Abstract:**

14 The capability of measuring 3-dimensional wind and tropopause structure with
15 relatively high time and vertical resolution makes VHF radar a potentially significant
16 tool for studying various processes of the atmosphere. Here the potential detection of
17 stratospheric intrusion events is discussed using the Beijing MST radar located at
18 Xianghe (39.75°N, 116.96°E). During the passage of a cut-off low in late November
19 2014, a deep V-shaped tropopause structure, and strong downdrafts (>0.8 m/s)
20 immediately preceding the rapid tropopause ascent (>0.2 km/h) were observed. Within
21 the height region of the downdrafts, the ‘normal’ radar-tropopause layer seems to be
22 weakened. Analysis results from global reanalysis and the satellite data, as well as the

23 trajectory model have shown the clear evidence of the downward stratospheric
24 intrusions (dry ozone-rich and depleted methane air) associated with the strong
25 downdrafts. According to the previous studies and the present case observation, the
26 strong downdrafts preceding rapid tropopause ascent are considered as a significant
27 signature of stratospheric intrusions. Twenty typical cases of such strong downdrafts,
28 occurring during various synoptic processes in different seasons, have been presented
29 and 16 of them are exactly associated with some form of stratospheric intrusions. Four
30 years (2012-2015) of such downdrafts are further discussed. The observations reveal
31 that the strong downdrafts preceding the rapid tropopause ascent can be a valuable
32 diagnostic for monitoring intrusion events, which will gain a better understanding of
33 stratospheric intrusions in VHF radar observations.

37

38 1. Introduction

39 The tropopause is a stable transition zone separating the vertically stable stratified
40 stratosphere from the active free troposphere. The stratospheric and tropospheric air are
41 remarkably different in their chemical and dynamical characteristics. The stratosphere
42 is dominantly high in ozone and potential vorticity (PV) content and low in water vapor
43 (WV) and methane (CH₄) concentration, while the troposphere is just on the contrary
44 (Holton et al., 1995). Consequently, the natural stable tropopause layer, characterized
45 by strong gradients of trace constituents and wind speeds, plays an important role in
46 stratosphere-troposphere exchange (STE) processes. In other words, the layer is a
47 significant barrier for the atmospheric transport between stratosphere and troposphere
48 (Mahlman, 1997). From a point of view, the long-term seasonal variation of the
49 tropopause height determines the seasonal variation of the flux of stratospheric air into
50 the free troposphere (Appenzeller et al., 1996). Under the global climate warming (e.g.
51 the continuing rise in CO₂), the tropopause variation is also a significant factor that
52 must be considered **with regards** to the recovery of the stratospheric ozone (Butchart et
53 al., 2010; Chipperfield et al., 2017). On the other hand, the short-term tropopause
54 variability is sensitive to various meso- and small-scale atmospheric processes, during
55 which the folding/intrusion events commonly occur. This characteristic of the
56 tropopause change are sometimes directly used to detect the tropopause folds (e.g. Rao
57 et al., 2008; Alexander et al., 2012, and references therein), but are less, if any, directly
58 used to identify stratospheric intrusions. More detailed analysis of the variability of
59 high-resolution tropopause height and of course some other parameters (e.g. 3-

60 dimensional wind), and how the stratospheric air is transported across the tropopause
61 into the troposphere will help us to yield better understanding of the downward
62 stratospheric intrusions (e.g. Sprenger et al., 2003; Leclair de Bellevue et al., 2007; Das
63 et al., 2016).

64 Although photochemical production within the troposphere is the main source of
65 tropospheric ozone, the influence of the downward stratospheric intrusions on the
66 tropospheric ozone content cannot be ignored (Oltmans and Levy II, 1992; Monks,
67 2000; Stevenson et al., 2006). Stratospheric intrusions bring dry ozone-rich air down
68 into the free troposphere (e.g. Stohl et al., 2000; Sørensen and Nielsen, 2001) and
69 sometimes even deep to the surface (e.g. Gerasopoulos et al., 2006; Ding and Wang,
70 2006; Lefohn et al., 2011). By now, it is well established that these intrusions of
71 stratospheric origin will significantly influence other trace gases (such as hydroxyl
72 (OH)) in the troposphere (Holton et al., 1995). These influences then will further
73 contribute to the change of radiative balance (Ramaswamy et al., 1992) and play an
74 important role in the radiative forcing of global climate change (Holton et al., 1995). It
75 is true that stratospheric intrusion events occur all over the world and in any season.
76 However, they are highly episodic in both vertical and isentropic (horizontal) directions
77 (Chen, 1995). Various dynamical and physical processes have been proposed to be
78 responsible for extra-tropical intrusion events. These mainly include tropopause folds,
79 stratospheric streamers and break-up, cut-off lows (COLs), wave breaking, and
80 mesoscale convective activities and thunderstorms (Stohl et al., 2003).

81 The certain dynamical and chemical characteristics of stratospheric air allow the

82 tracers, such as dry ozone-rich and high PV, to be proper indicators for the intrusions
83 penetrating down into the troposphere. Various methods are available to detect intrusion
84 events based on these tracers. Among them, balloon-borne ozonesonde sounding are
85 without doubt one of the most appropriate tools, but is limited by coverage (He et al.,
86 2011) and not possible to obtain continuous profiles with fine temporal resolution. In
87 contrast, the satellite-borne remote sensing instruments, such as Atmospheric Infrared
88 Sounder (AIRS), can provide nearly global coverage of various trace gases but have
89 limitations in vertical and temporal resolution. Another method for studying transport
90 processes is trajectory model, from which the backward trajectories can provide
91 valuable information on the possible sources of the trace gases (e.g. Elbern et al., 1997).

92 By far, large-scale STE has been widely studied and is fairly well understood, but
93 the details of small scale intrusions still remain uncertain (Holton et al., 1995). Kumar
94 and Uma (2009) reported that the dearth of direct vertical wind measurements in the
95 vicinity of the tropopause may be responsible for the lack of detailed fine observations
96 of smaller scale intrusions.

97 Very-High-Frequency (VHF) radars, compared to the tools mentioned above, are
98 capable to provide 3-dimensional wind and tropopause height continuously with both
99 high temporal and spatial resolution and can operate unmanned continuously for 24
100 hours per day under any weather conditions. During the past two decades, VHF radar
101 measurements were commonly used to assist to study the stratospheric intrusions.
102 However, it still remains uncertain in many aspects when using only the VHF radar to
103 identify intrusion events. Complicated and changeable atmospheric processes make it

104 difficult to identify the intrusion events by only radar data. The research by Hocking et
105 al., (2007) have achieved a development in this issue. They found that the rapid ascent
106 in radar tropopause altitude (>0.2 km/h) can be a valuable diagnostic for possible
107 stratospheric intrusions and the RT height started to ascent when the stratospheric air
108 just intruded across the tropopause layer. However, it does not always work (e.g. He et
109 al., 2011) and remains uncertain when purely using the information of radar-determined
110 tropopause.

111 The central objective of the present study is to discuss the signature of downward
112 cross-tropopause intrusions using both the measurements of tropopause height and
113 vertical wind by the Beijing MST radar. This study is carried out mainly via a detailed
114 case observation during the passage of a COL and other general cases associated with
115 various atmospheric processes. Our discussion mainly focused on the potential of the
116 MST radar data to identify possible intrusion events, which is the main point of this
117 paper. In section 2 the datasets used in this paper are described, section 3 presents
118 detailed results and discussion, and section 4 gives the conclusions.

119

120 2. Dataset

121 2.1. MST radar data and tropopause detection

122 The Beijing MST radar located at Xianghe, China (39.75° N, 116.96° E, 22 m
123 above sea level) is a VHF radar operated at 50 MHz and installed in 2010 based on the
124 first phase of Chinese Meridian Space Weather Monitoring Project (Chinese Meridian
125 Project for short) (Wang, 2010). The radar antenna array consists of 24×24 three-
126 element Yagi to produce an average power aperture product of 3.2×10⁸ Wm² and
127 maximum directive gain of 34.8 dB. It operates radiation pattern with 172 kW peak
128 power and 3.2° half-power beam width. More detailed information of the radar system
129 can be found in Chen et al. (2016). Routine low mode data were used for present study
130 with 0.5 h time resolution and 1 μs coded pulse, which provides 150 m vertical
131 resolution. Details of the low mode setup used in this study are given in Table 1.

132 It has long been known that VHF radar reflectivity is proportional to the mean
133 generalized refractive index gradient M , which is a function of humidity variation and
134 static stability and given by (Ottersten, 1969) as follows

$$135 \quad M = -77.6 \times 10^{-6} (p/T) (d \ln \theta / dz) \\ 136 \quad \cdot \{ 1 + 15500 q / T [1 - (d \ln q / dz) / (2 d \ln \theta / dz)] \} \quad (1)$$

137 where p is the atmospheric pressure (hPa) T is the temperature (K), θ is the potential
138 temperature (K) and q is the specific humidity (gg⁻¹). According to the second and third
139 terms of the equation (1): large humidity variation contributes to the echo from the
140 lower and middle troposphere. From the first term: the radar backscatter power is
141 proportional to the static stability, which in fact is directly proportional to the potential

142 temperature gradient. The tropopause, near which a strong potential temperature
143 gradient exists, will lead to strong radar echoes in vertical incidence, as well as large
144 radar aspect sensitivity (as shown in Figure 1). Radiosonde data used in this paper were
145 received from the GTS1 type digital radiosonde launched from Beijing Meteorological
146 Observatory (39.93 °N, 116.28 °E, station number 54511), which is less than 45 km
147 away from the MST radar site. The black line in Fig.1 denotes the lapse-rate tropopause
148 (LRT) defined using the temperature lapse rate (World Meteorological Organization
149 (WMO), 1986). Applying the characteristic (enhanced radar echoes due to partial
150 specular reflection) mentioned above, the tropopause can be detected and its height
151 determined by VHF radars (Gage and Green, 1979). It has received widespread
152 application around the world, either in middle latitudes (e.g. Hocking et al., 2007), polar
153 regions (e.g. Alexander et al., 2012), and tropical regions (e.g. Yamamoto et al., 2003;
154 Das et al., 2008). Here, the radar-determined tropopause (RT) height is defined as the
155 height (above 500 hPa) where the maximum vertical gradient of echo power located
156 (shown as the orange circle in Figure 1a). This definition of RT is similar to that in the
157 studies of Alexander et al., 2012 and Ravindrababu et al., 2014.

158 In the present study, the MST radar mainly provides continuous measurements of
159 backscattered echo power, 3-D wind, and RT height with time resolution of 0.5 hour. In
160 addition, the radar aspect sensitivity, expressed as the ratio between vertical (p_v) and
161 oblique (p_o) beam echo power, is mainly caused by the horizontally stratified
162 anisotropic stable air and thus will be used as potential signature of stratospheric
163 intrusions in the troposphere (e.g. Kim et al., 2001). The backscattered echo power

164 given here is expressed as relative power in decibels (dB). In order to reduce the random
165 noise, the profile of p_v is smoothed by a 3-point running mean in altitude. Note that
166 the data that are heavily contaminated will be eliminated from our datasets. The data of
167 Dec. 2015 and Sep. 2015 are excluded.

168 2.2. AIRS satellite data

169 The AIRS instrument on NASA Aqua/EOS polar orbit satellite is a 2378 channel
170 nadir cross-track scanning infrared spectrometer. It can provide profiles of a number of
171 trace gases, including ozone and CH₄ (Susskind et al., 2003). The footprint of these
172 retrieval data is of 45 km by 45 km and their most sensitive region is in an altitude range
173 of 300-600 hPa. Many studies have shown that these AIRS retrieval constituents are
174 useful indicators for detecting stratospheric intrusions. He et al. [2011] suggested that
175 AIRS can observe the enhanced tropospheric ozone that is of stratospheric origin.
176 Xiong et al. [2013] reported that AIRS is capable of observing abnormal depletion in
177 CH₄ in the troposphere during intrusions. AIRS offers good latitude-longitude coverage.
178 Here we use version 6 of the AIRS Level-3 ozone and methane retrieval products.

179 2.3. Meteorological reanalysis

180 European Centre for Medium-Range Weather Forecasts (ECMWF) reanalysis
181 ERA-interim data are also used. After Nov. 2000 the data are based on the T511L60
182 version available with a 6-h temporal resolution and $3^\circ \times 3^\circ - 0.125^\circ \times 0.125^\circ$
183 latitude-longitude grid. The dataset from 15 isentropic and 37 pressure levels
184 **interpolated into** $0.5^\circ \times 0.5^\circ$ grid are applied for present study.

185 2.4. HYSPLIT model

186 Backward (forward) trajectories in given starting locations are capable to
187 reproduce the sources (destinations) of the air parcel that will allow us to examine the
188 intrusions of stratospheric origin in the troposphere (e.g. Elbern et al., 1997). The
189 Hybrid Single Particle Lagrangian Integrated Trajectory model (HYSPLIT) developed
190 by the National Oceanic and Atmospheric Administration (NOAA)'s Air Resource
191 Laboratory (ARL) (Rolph, 2003; Stein et al., 2016) is applied to calculate the backward
192 and forward trajectories. The calculation method of the model is a hybrid between the
193 Lagrangian approach and the Eulerian methodology. In this paper, Global Data
194 Assimilation System (GDAS) datasets are adopted for driving the HYSPLIT.
195

196 **3. Results and discussion**

197 3.1. Meteorological synoptic situation

198 On the morning of 29 November 2014, a 500-hPa trough developed on the western
199 side of Lake Baikal (Western Siberia). The trough moved southeastward and extended
200 equatorward and its southern tip separated from the westerlies in the afternoon of 30
201 November 2014 (Fig. 2b), forming a COL near the radar site as shown by the closed
202 geopotential contour. The black stars in Figure 1 and other figures indicate the location
203 of the radar site. On the following days, the COL system moved northeastward
204 gradually (Fig. 2b) and finally stayed over eastern Russia near Sakhalin Island until it
205 reconnected and merged to the westerly flow. 315 K isentropic PV patterns have shown
206 the coarse resolution features of intrusions from the polar reservoir across the
207 tropopause into the midlatitude troposphere. The PV streamer curved and rolled up
208 cyclonically along the western flank of the COL (Fig.2b).

209 Fig. 3 shows the time series of hourly surface meteorological parameters over the
210 Beijing station. The data are obtained from the Chinese National Meteorology
211 Information Center and is less than 50 km from the MST radar site. As the dry-cold air
212 invasion accompanied with the COL travelled deeply into the planetary boundary layer,
213 it brought severe weather to the surface, including a rapid decrease in temperature and
214 humidity, and rapid increase in surface wind and sea level pressure. The humidity
215 decreased from ~85 to 12 percent within less than 8 hours. It is well established that the
216 polar-type COLs have strong potential to trigger deep convection (Price and Vaughan,
217 1993). To examine the potential convection, maps of high quality Climate Data Record

218 (CDR) of daily Outgoing Longwave Radiation (OLR) are displayed in Fig. 4. During
219 the development of the COL, a local region with abnormal low OLR value was clearly
220 observed near the radar site on 29 Nov. (Fig. 4b). The Satellite-observed cloud top
221 temperature also showed the low values corresponding to the low OLR (figure not
222 shown), indicating **that** convection may be generated near radar side on 29 Nov.. Please
223 note that we **did not** observe such low value either in OLR (Fig.4c, d) or in cloud top
224 temperature near the radar side on 30 Nov. and 1 Dec.. The time for all the observations
225 in this paper is **shown** in Universal Time (UTC) which is eight hours behind Beijing
226 standard time (LT=UTC+8).

227 **3.2. MST radar observations**

228 Radar echo power, horizontal wind vector, vertical wind, and radar aspect
229 sensitivity are plotted in Figure 5 as function of height and time during the passage of
230 the COL. Time variation of RT (black line) and LRT (black crosses) heights are also
231 displayed. The RT height first experienced a rapid descent, and then increased rapidly,
232 forming a deep V-shaped structure of ~4 km depth. The vertical velocity of the RT
233 height variation (both the rapid descent and ascent branches) reaches up to 0.28 km/h.
234 The rapid RT variation in altitude is in fact the response of the tropopause fold below
235 the jet stream, which will be well represented in Fig. 8a. Rapid variation in RT height
236 remained a region with low echo power (marked by R on Fig. 5a) and low aspect
237 sensitivity (marked by R' on Fig. 5d) where they should be normally high value within
238 the 'normal' tropopause layer. Unlike the RT height, the radiosonde LRT altitudes are
239 nearly constant during the COL passage. In normal conditions, RT agrees well with the

240 LRT altitude, such as indicated by Fig. 6a. However, large differences, of order of 2.5
241 km (as shown in Fig.6b at 12 UTC 30 Nov.), are observed between LRT and RT in
242 altitude during the passage of the COL as expected. It is the difference in definition that
243 contribute most to the large differences, especially under the tropopause fold conditions.
244 It is worth noting that, in Fig.6b, although there is no clear reversion in the radiosonde
245 temperature profile within the height of RT, the RT height exactly corresponds well to
246 the reversion of zonal and meridional wind and potential temperature gradient. Such
247 differences between RT and LRT heights can commonly be observed, especially during
248 extreme synoptic situations such as cyclone (e.g. Alexander et al., 2012).

249 The most important observation in this detailed case experiment is the strong
250 downdrafts (hereinafter inferred to as main downdrafts) observed immediately
251 preceding the rapid RT ascent (Fig.5c). The radar echo power sharply weakened (dotted
252 rectangle in Fig.5a) and the wind direction changed rapidly (Fig.5b, change from
253 dominant southerly wind to dominant northerly jet) within the height region of the main
254 downdrafts. As mentioned previously, abnormal low value in OLR and cloud top
255 temperature indicates the possible occurrence of convective activity on 29 Nov., but
256 nothing special appeared on 30 Nov. near radar site. Consequently, we preliminarily
257 consider that the main downdrafts occurred near 07 UT 30 November might not be
258 produced directly by convective activity. Here, the accurate origin of the main
259 downdrafts will not be discussed in detail, and it is also beyond the scope of present
260 study.

261 The research by Hocking et al. (2007) has suggested that the rapid RT ascent (>0.2

262 km h⁻¹) can be a valuable indicator for the occurrence of stratospheric intrusions. Here
263 in this paper, the main downdrafts preceding the rapid RT ascent observed by the
264 Beijing MST radar are thus suspected to be an important feature or response of some
265 form of vertical stratospheric intrusions. Firstly, as the tropopause descends (folded
266 downward), it will displace stratospheric air into the troposphere (e.g. Hoskins et al.,
267 1985). Secondly, the main downdrafts will act as an effective way to weaken the
268 tropopause by means of continuously **impinging** on the tropopause, through which the
269 stratospheric air is permitted to penetrate down into the free troposphere (e.g.
270 Hirschberg and Fritsch, 1993; Kumar, 2006). In addition, after the main downdrafts,
271 the observed region near the upper troposphere with strong backscatter echoes (marked
272 by Q) and especially with abnormal high aspect sensitivity (marked by Q') may also be
273 a weak signature of the possible intrusions. In normal conditions in the upper-
274 troposphere, they are usually low in value (such as the region marked by P and P'). As
275 we mentioned before, the large value in radar aspect sensitivity is mainly caused by
276 reflection from stable atmospheric layer, such as the tropopause or lower-stratosphere.
277 When stable stratospheric air intrudes into the troposphere and without mixing with the
278 surrounding air mass, the intrusions in the free troposphere will be reflected as
279 abnormal large aspect sensitivity. Further direct evidence of the relevant intrusions in
280 dynamical and chemical aspects will be demonstrated in next section, using satellite
281 AIRS and global reanalysis data.

282 3.3. Associated stratospheric intrusions

283 Due to the sensitivity of the AIRS retrieved ozone and CH₄ is between 300-600

284 hPa. Fig. 7 shows the 500 hPa distribution of AIRS observed ozone and CH₄, along
285 with the AIRS tropopause contour (defined based on the temperature lapse-rate). The
286 ozone distribution maps (left panels of Fig. 7) clearly show a large area with enhanced
287 tropospheric ozone (>80 ppbv) near the radar site during the passage of the COL.
288 Moreover, severe CH₄ depletion (<1840 ppbv) was also observed (right panels in Fig.8).
289 These features of the ozone enhancement, CH₄ depletion, and the corresponding low
290 tropopause altitude clearly support the evidence of vertical downward cross-tropopause
291 stratospheric intrusions on 30 Nov..

292 The vertical cross-section of ECMWF PV and specific humidity at 1800 UT 30
293 November 2014 and the daily AIRS ozone on 30 November 2014, along a constant
294 latitude 40° N, is shown in Fig. 8. The corresponding vertical structure of the
295 stratospheric intrusions (dry ozone-rich and high PV along with low tropopause) over
296 regions near radar side is clearly seen. The specific humidity tracer displays less distinct
297 structure as compared with the other two tracers (similar as that shown by Vérémes et
298 al., 2016). The cross-section of PV in Fig. 8a have demonstrated relatively finer-scale
299 structure of the stratospheric PV intrusions (below the jet stream), which penetrated
300 down deeply into ~650 hPa (~3.6 km).

301

302 3.4. Trajectory model analysis

303 Figure 9 shows 30h backward trajectories ending at the radar site at 18 UT 29
304 November (left panel) and at 18 UT 30 November (right panel). As expected, the air
305 masses parcel transported eastward horizontally before the occurrence of main

306 downdrafts (fig.10a). Whereas after the downdrafts, the trajectories clearly show that
307 the tropospheric air masses over the radar site are of stratospheric origin from the
308 western side of Lake Baikal. Trajectory results further support the evidence of
309 stratospheric intrusions that closely related with the main downdrafts.

310 On the other hand, 30-h forward trajectories starting at 00 UT 30 November (left
311 panel) and 00 UT 1 December (right panel) are shown in Fig. 10. It is interesting to note
312 that, from Fig.11a before the passage of COL, the air parcels at 4 km transport rapidly
313 upward (by more than 4 km within ~23 h) and northeastward to the upper-troposphere
314 of East Siberian. This upward and poleward transportation is associated with a warm
315 conveyor belt (**southerly flows dominate**) that is located ahead of the COL. It
316 contributes to transporting the tropospheric moist and polluted air (such as aerosol) into
317 the upper-troposphere and even the lower stratosphere (e.g. Stohl et al., 2003; Sandhya
318 et al., 2015). After the downdrafts, forward trajectories in fig.11b demonstrate that the
319 dry intrusion air parcels continue to be transported downward and southeastward to the
320 boundary layer or even the surface.

321 3.5. Strong downdrafts preceding rapid tropopause ascent and discussion

322 Figure 11a shows another 20 typical cases **of** strong downdrafts preceding rapid
323 RT ascent for the period Mar. 2012 and Jan. 2015 (shown placed end-to-end), the LRT
324 height (plotted in crosses) and the vertical velocity of the RT (plotted in orange line) is
325 also plotted. These cases (**marked by black rectangular boxes and labeled as S1, S2,**
326 **S3..., and S20**) are identified based on the following criteria: 1) the amplitude of the
327 RT ascent should exceed 0.6 km (four range gates), 2) vertical velocities of the RT

328 ascent excess 0.1 km/h, 3) the downdrafts occurred preceding the RT ascent **should >0.5**
329 m/s, and the height region of the downdrafts should pass through the RT layer. The
330 criteria are put forward mainly to avoid the influence of the RT spikes. Figure 11b
331 **shows the backward trajectories for the selected 9 cases.** Results show clear evidence
332 of **downward intrusions** corresponding to the associated strong downdrafts. Their
333 sources are mainly from West Siberia (western side of Lake Baikal), except for the case
334 Tr5. Moreover, according to AIRS daily 500 hPa ozone distribution, **most of the cases**
335 in Figure 11a (except for the cases S14, S15, S16, S17, S20) were **associated with**
336 **significant ozone enhancement**, indicating intrusions of stratospheric origin (as shown
337 in **Supplementary figure S1**). It is important to note that the RT excursion velocity of
338 all the cases is not all above 0.2 km/h and some are lower than this value (**e.g. cases**
339 **S16 and S18**). However, some form of stratospheric intrusions **was** exactly observed in
340 **such cases** from both the trajectory and satellite results. Therefore, the threshold of
341 vertical velocity of the RT **ascent** is set at 0.1 km/h, rather than 0.2 km/h (Hocking et
342 al., 2007). Large differences between RT and LRT are also interesting to be noted on
343 some occasions when the RT changes rapidly (such as the occasion near 14 Mar. 2012).

344 According to the meteorological chart, the synoptic situation of those cases
345 identified in **Fig. 11a** are introduced. The **cases S1, S2, S8, S9, S10, and S11** seem to
346 have a close relationship with COL development; **cases S3, S4, S5, S6, S7, S17, S18,**
347 **and S19** seem associated with low or high **trough systems (at 500 hPa)**. The remaining
348 cases seem not associated with any significant synoptic development. However, in
349 terms of the distribution of isentropic PV (generally at 315K in winter and 330K in

350 summer), we found that the remaining cases S12, S13, S14, S15, S16, and S20 appear
351 to be associated with some form of stratospheric streamers and their break-up within
352 the previous 48h (not shown). Some cases (e.g. S1 and S2) that appear close on the
353 same day were probably caused by the same system. The characteristics of the 20 cases,
354 including background synoptic condition, vertical velocity of the RT ascent, and 500
355 hPa ozone enhancement, have been summarized in Table 2.

356 In the light of present understanding, the strong downdrafts preceding the rapid
357 RT ascent can serve as an important diagnostic for intrusion events, during various
358 synoptic processes in any season. This characteristic will be of great use and play an
359 important role in routine identification of stratospheric intrusions. Considering the
360 duration of such downdrafts, a higher time resolution of radar observations will be more
361 helpful. Present study has shown the duration of the majority downdrafts is generally
362 within 1.5-3 hours. We consider, therefore, that the radar resolution should be best
363 within 1h.

364 Although Hocking et al. (2007) have reported that the rapid tropopause ascent
365 (>0.2 km/h) alone can be a useful diagnostic for potential intrusion events. However,
366 using only the information of RT heights might lead to non-negligible errors, as
367 mentioned above in introduction and according to the observations in Fig. 11.
368 Especially on occasions when the RT ascent is between 0.1-0.2 km/h but the
369 corresponding true intrusions were observed, all such intrusion events will be neglected
370 (maybe ~ 2 per month, refer to Fig. 12a). Whereas on some occasions when the RT
371 ascent exceeds 0.2 km/h, but without observing true intrusion events (e.g. He et al.,

372 2011), these events will be misdiagnosed (maybe ~13 per month, refer to Fig. 12b). In
373 this sense, using the unique MST radar observations of both the RT height variability
374 and the vertical wind as complementary signature for identifying possible intrusion
375 events is very meaningful.

376 Figure 12 shows four years (2012-2015) of the events with rapid RT ascent (gray
377 bands), and the events with strong downdrafts just preceding the rapid RT ascent (black
378 bands). The identification criteria of such strong downdrafts are similar to that
379 mentioned above and the events are classified according to different value of vertical
380 velocity of the ascent. Among all the events with ascent velocity between 0.1-0.2 km/
381 h, about one-quarter (approximate 2 per month, Fig. 12a) were observed with strong
382 downdrafts preceding them. Whereas, as for the events with the ascent velocity >0.2
383 km/h, the proportion is about a half (approximate 10 per month, Fig. 12b). Here,
384 according to the results above, the occurrence of the strong downdrafts just preceding
385 the rapid RT ascent (black bands in Fig. 12) to a large degree represents the occurrence
386 of possible intrusions. In this way, Fig. 12 indicates that the occurrence of possible
387 intrusions exhibit distinct seasonal variations, with a maximum in winter and spring
388 minimum in summer. This is because the meso- and small-scale atmospheric processes,
389 such as cold air outbreaks, thunderstorms, and convective activities, are more active in
390 winter and spring. They are important sources for downward stratospheric intrusions.

391

392 4. Conclusions

393 Detailed case analysis of the cross-tropopause stratospheric intrusions was carried
394 out during a COL. Global reanalysis, satellite data, and HYSPLIT trajectories all
395 showed consistent evidences of dry ozone-rich, high PV, and depleted CH₄ air that have
396 penetrated downward into the free troposphere. The key signature of the stratospheric
397 intrusions in the Beijing MST radar observations is the strong downdrafts just preceding
398 rapid RT ascent. The radar echo power decreased rapidly within the region of strong
399 downdrafts, after which abnormal high aspect sensitivity was recorded in troposphere.
400 Such high aspect sensitivity is served as another potential clue for the intrusions of
401 stratospheric origin.

402 Based on the criteria mentioned in section 3.5, other 20 typical cases of strong
403 downdrafts preceding the rapid RT ascent between Mar. 2012 and Jan. 2015 were
404 presented. These events occurred during different synoptic processes in different
405 seasons. **Yet, most of the cases (15 of them)** are associated with some form of intrusions
406 observed by combination of **AIRS-retrieved** ozone and the HYSPLIT trajectory model.
407 Our results show that the **radar-derived** tropopause height and vertical winds are strong
408 complementary indicators to be used to infer the occurrence of the intrusions of
409 stratospheric origin. This will be of great use and play an important role for the routine
410 identification or prediction of intrusion events. However, the actual origin of the
411 observed downdrafts preceding the rapid RT ascent is not addressed in this paper.
412 Further combination observational experiments need to be conducted, especially
413 combined using ozonesonde soundings, to quantitative analyze the effectiveness of

414 present identification criteria for possible intrusions.

415

416

417 **Acknowledgment**

418 The authors really appreciate Prof Shira Raveh-Rubin for reading and checking the
419 manuscript, using the criterion in Raveh-Rubin, 2017. This work is funded by National
420 Natural Science Foundation of China (NSFC grants No. 41722404 and 41474132). The
421 authors would like to thanks the technical and scientific staff of Chinese Meridian Space
422 Weather Monitoring Project (CMSWMP) for their support in conducting the
423 experiment. The authors sincerely acknowledge the ECMWF, NASA, and NOAA Air
424 Resources Laboratory (ARL) for providing global reanalysis, satellite trace gases, and
425 HYSPLIT transport model, respectively. The MST radar data for this paper are
426 available at Data Centre for Meridian Space Weather Monitoring Project
427 (<http://159.226.22.74/>). The radiosonde data is available from
428 <http://weather.uwyo.edu/upperair/sounding.html>.

617 **Figure 3.** Time series of surface (~ 1.2 m above the surface) hourly meteorological

618 measurements of (a) sea level pressure, (b) temperature, (c) relative humidity, (d)

619 horizontal wind, and (e) meridional wind during the period 24 Nov.-6 Dec. 2014,

620 observed over the Beijing station (39.4° N, 116.2° E, 31.3 m above sea level).

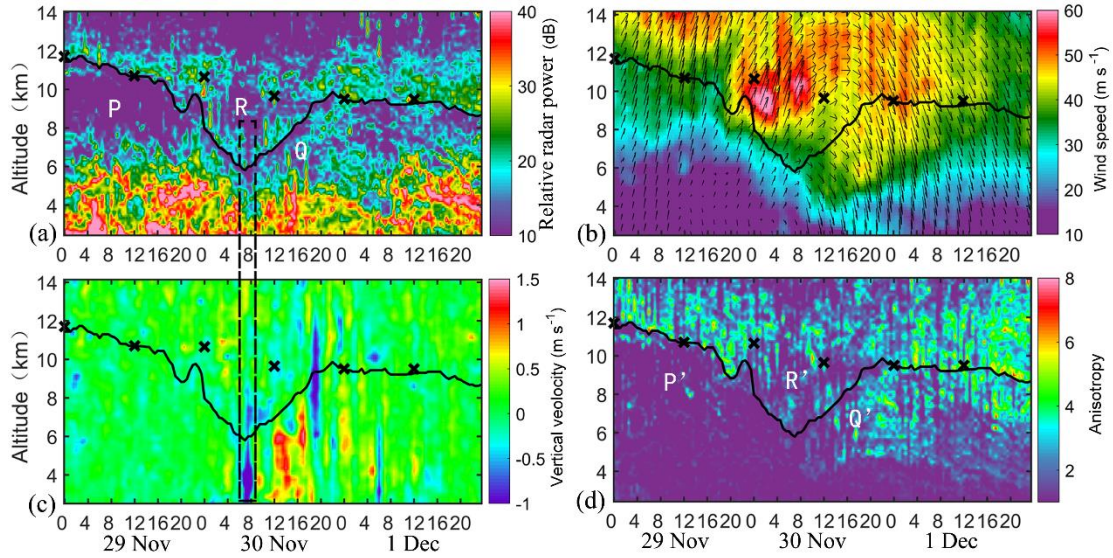

621

622

623 **Figure 4.** Contour maps of the high quality Climate Data Record (CDR) of the daily
 624 Outgoing Longwave Radiation (OLR), derived from the NOAA high-resolution
 625 infrared radiation sounder (HIRS) on (a) 28 Nov., (b) 29 Nov., (c) 30 Nov., and (d) 1
 626 Dec. 2014. The black star shows the location of Xianghe.

627

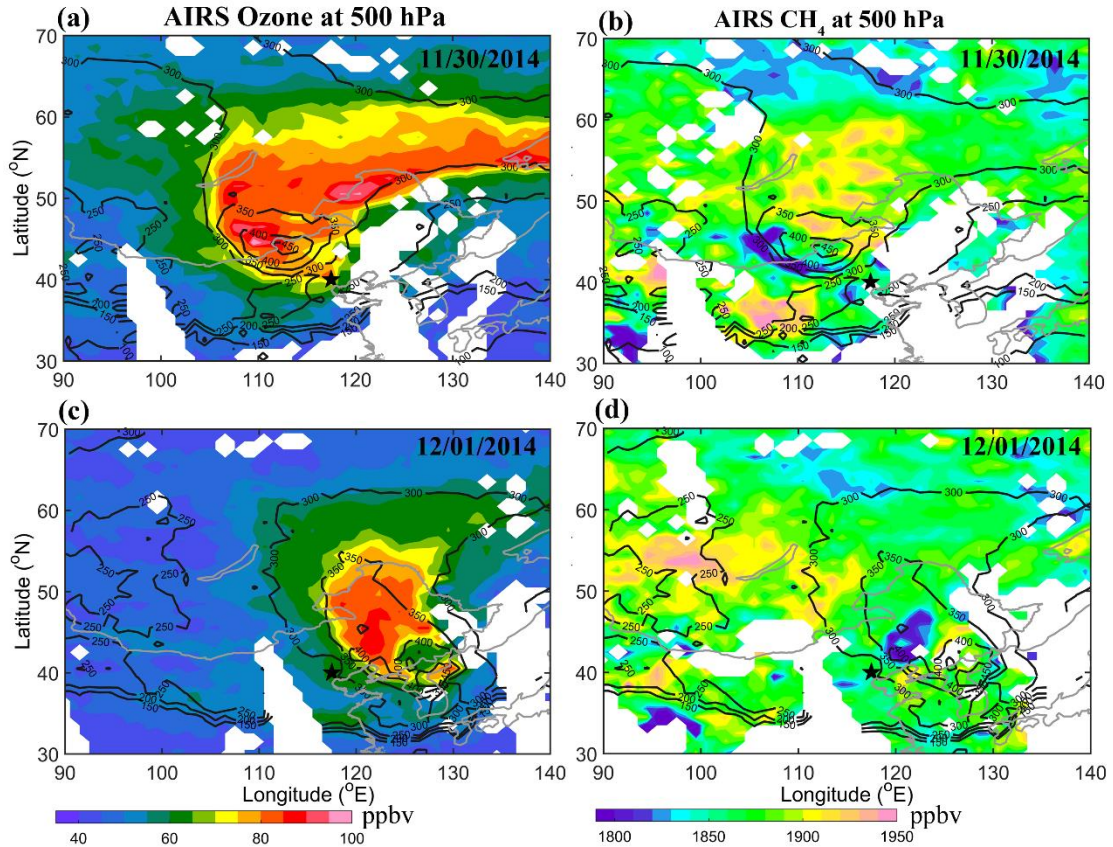

628

629 **Figure 5.** Altitude-time section of (a) the radar backscattered echo power in zenith
 630 direction, (b) the horizontal wind speed along with wind vector, of which the up and
 631 down arrows represent north and south respectively, and left-right is west-east, (c) the
 632 vertical velocity, and (d) the aspect sensitivity, observed by the Beijing MST radar from
 633 29 November to 1 December 2014. The black curve shows the radar-determined
 634 tropopause, as defined in section 2.1. The dotted rectangle highlights the strong
 635 downdrafts immediately preceding the rapid tropopause ascent. The positions of the
 636 LRT tropopause heights, derived from the nearly simultaneous collocated GPS
 637 radiosonde temperature profile, are marked by crosses.

639 **Figure 6.** Vertical profiles of zonal wind, meridional wind, temperature, and potential
 640 temperature gradient derived from the GPS radiosonde measurements, at (a) 0000 UTC
 641 29 November 2014 and (b) 1200 UTC 30 November 2014. The bold arrows on the left
 642 and right side of each panel indicate the radiosonde derived LRT tropopause and radar-
 643 derived tropopause height, respectively.

644

645

646 **Figure 7.** 500 hPa Ozone (left panels) and methane CH₄ (right panels) distribution

647 along with the tropopause height contour, derived from the AIRS satellite observations.

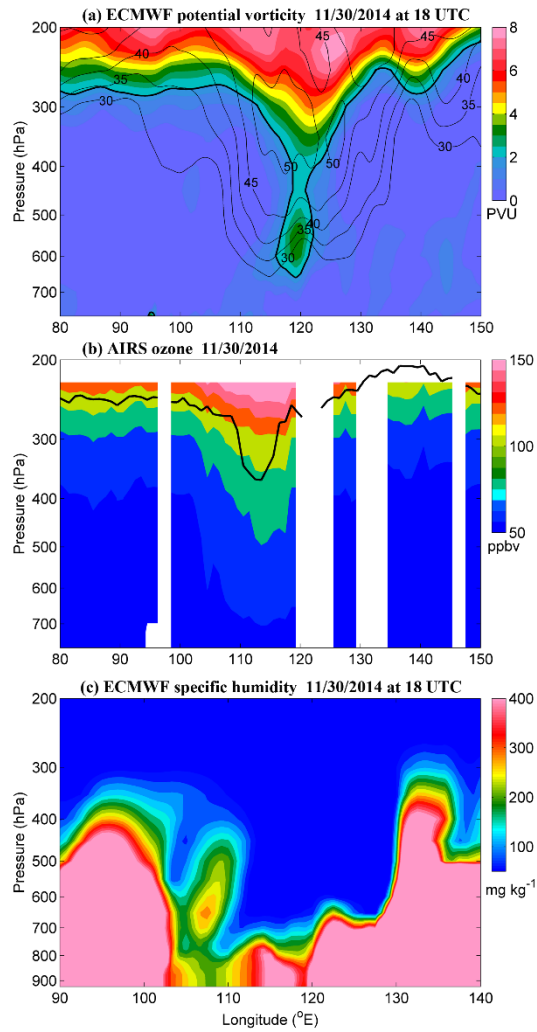

648 The top and bottom plots show the data of 30 Nov. 2014 and 1 Dec. 2014, respectively.

649 According to the Aqua Orbit Tracks (not shown), the time range of the satellite passage

650 is between ~04:00-07:25 on 30 November and between ~03:15-06:35 on 1 December

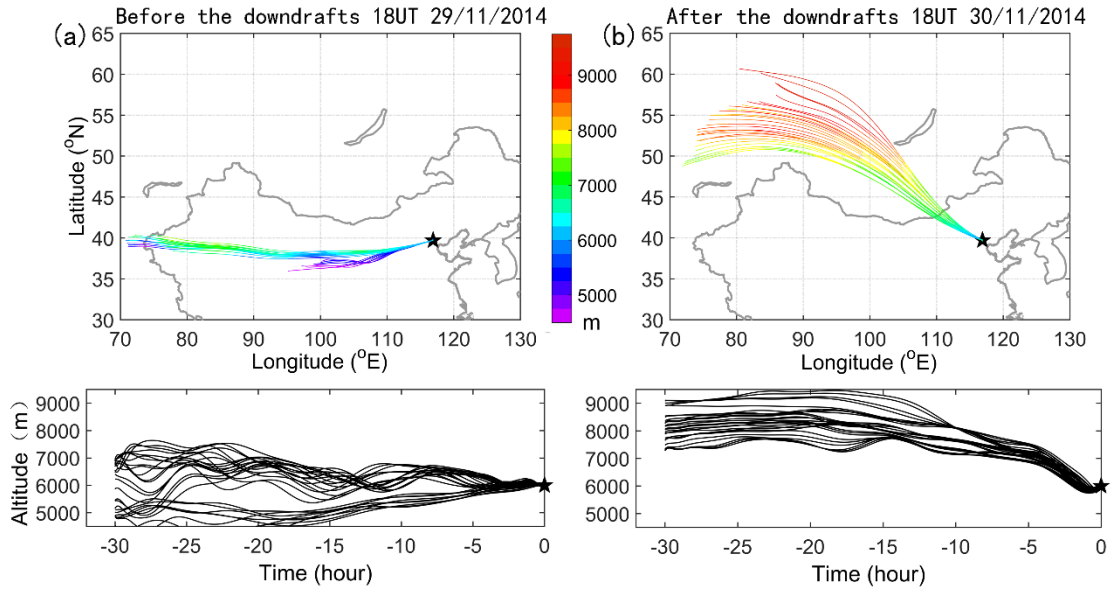

651 2014. The black star indicates the location of Xianghe.

652

653

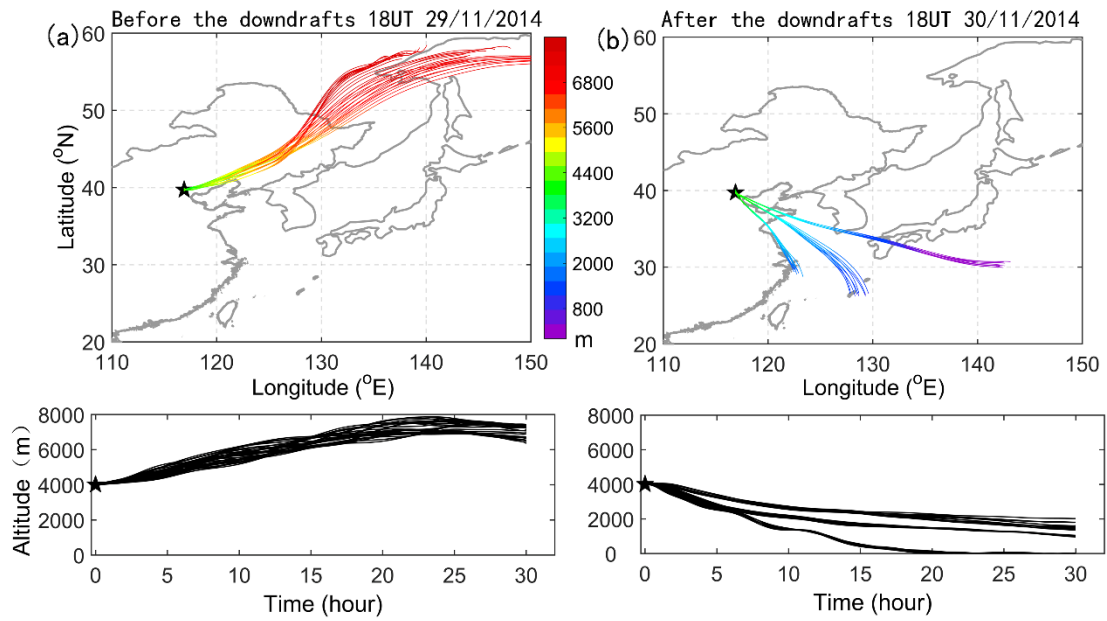

654 **Figure 8.** Longitude-pressure cross section of (a) ECMWF PV (colors, in pvu) along
 655 with horizontal wind contour (thin black line, m/s) at 18 UTC on 30 Nov. 2014, (b)
 656 AIRS ozone mixing ratio (colors, in ppbv) along with tropopause height (black line) on
 657 30 Nov. 2014, and (c) ECMWF specific humidity (colors, in mg kg^{-1}) at 18 UTC on 30
 658 Nov. 2014, at a constant latitude 40° N (nearest grid point in the latitude of Xianghe).
 659 The bold line in (a) marks the isotropic line of PV at 2 pvu.

660

661 **Figure 9.** Illustration of 30 h three-dimensional backward trajectories ending at
 662 Xianghe at 6000 m using National Oceanic Atmospheric Administration (NOAA)
 663 HYSPLIT model: (a) before the main downdrafts at 18 UTC on 29 November 2014,
 664 and (b) after the main downdrafts at 18 UTC on 30 November 2014. The HYSPLIT
 665 ensemble consists of 27 trajectories. Upper plots show the horizontal projection of the
 666 trajectories, and the lower plots show the corresponding time-height vertical
 667 displacement of the trajectories.

668

669

670 **Figure 10.** Same as Fig.10 but for three-dimensional forward trajectories starting at

671 Xianghe at 4000 m: (a) before the main downdrafts at 00 UTC on 30 November 2014,

672 and (b) after the main downdrafts at 00 UTC on 1 December 2014.

673

674 **Figure 11.** (a) Height-time section of several episodic observations of the radar-derived
 675 vertical wind (colors in m/s) along with RT height (purple bold line) and LRT height
 676 (bold crosses), between Mar. 2012 and Jan. 2015. The corresponding vertical velocity
 677 of the RT (orange line) is plotted in the lower panel of (a), dotted blue line indicates the
 678 value of 0.2 km/h. Dates for the observations are displayed as year/month/day. Black
 679 rectangular boxes represent **the cases of strong downdraughts (absolute value ≥ 0.5 m/s)**
 680 **preceding rapid tropopause ascent (>0.1 km h⁻¹) and are labeled as S1, S2, S3..., S20.**

681 Symbol ‘*’ labeled as Tr1-Tr9 indicates the ending point of the corresponding
682 trajectories in Fig.12b. (b) Results of backward trajectories (colors in km) of the typical
683 9 selecting cases from Fig.12a, providing the signature and source of possible
684 stratospheric intrusions.
685

686

687 **Figure 12.** Four years (2012-2015) of radar-determined monthly mean number of rapid

688 tropopause ascent (gray bands) and the corresponding strong downdrafts just preceding

689 the rapid tropopause ascent (black bands). (a) Gray bands: with the ascent by at least

690 0.6 km and the excursion velocity is between 0.1-0.2 km h⁻¹; black bands: except for

691 the criteria of gray bands, strong downdrafts occurred preceding the rapid RT ascent

692 must exceed 0.5 m s^{-1} and pass through the RT layer. (b) Same as (a) but for the
693 occasions when the ascent velocity is larger than 0.2 km h^{-1} . According to the study
694 here, the black bands in the histogram well represent the occurrence of possible
695 stratospheric intrusions.
