13 **Abstract:**

14 The capability of measuring 3-dimensional wind and tropopause structure with
15 relatively high time and vertical resolution makes VHF radar a potentially significant
16 tool for studying various processes of the atmosphere. In the light of present
17 understanding, using VHF radars to identify possible stratospheric intrusions still
18 remain unclear. Here the potential detection of stratospheric intrusion events is
19 discussed using the Beijing MST radar located at Xianghe (39.75°N, 116.96°E). During
20 the passage of a cut-off low in late November 2014, a deep V-shaped tropopause
21 structure, and strong downdrafts (>0.8 m/s) immediately preceding the rapid tropopause
22 ascent (>0.2 km/h) were observed. Within the height region of the downdrafts, the

23 stability of the radar tropopause seems to be weakened. Analysis results from global
24 reanalysis and the satellite data, as well as the trajectory model have shown the clear
25 evidence of the downward stratospheric intrusions (dry ozone-rich and depleted
26 methane air) associated with the strong downdrafts. Twenty typical cases of such strong
27 downdrafts, occurring during various synoptic processes in different seasons, have been
28 presented and 15 of them are exactly associated with some form of stratospheric
29 intrusions. Four years (2012-2015) of such downdrafts are further discussed. The
30 observations reveal that the strong downdrafts preceding the rapid tropopause ascent
31 can be a valuable diagnostic for monitoring intrusion events, which will gain a better
32 understanding of stratospheric intrusions in VHF radar observations.

36

37 **1. Introduction**

38 The tropopause is a stable transition zone separating the vertically stable stratified
39 stratosphere from the active free troposphere. The stratospheric and tropospheric air are
40 remarkably different in their chemical and dynamical characteristics. The stratosphere
41 is dominantly high in ozone and potential vorticity (PV) content and low in water vapor
42 (WV) and methane (CH₄) concentration, while the troposphere is just on the contrary
43 (Holton et al., 1995). Consequently, the natural stable tropopause layer, characterized
44 by strong gradients of trace constituents and wind speeds, plays an important role in
45 stratosphere-troposphere exchange (STE) processes. In other words, the layer is a
46 significant barrier for the atmospheric transport between stratosphere and troposphere
47 (Mahlman, 1997). From a long-term point of view, the seasonal variation of the
48 tropopause height determines the seasonal variation of the flux of stratospheric air into
49 the free troposphere (Appenzeller et al., 1996). Under the global climate warming (e.g.
50 the continuing rise in CO₂), the tropopause variation is also a significant factor that
51 must be considered with regards to the recovery of the stratospheric ozone (Butchart et
52 al., 2010; Chipperfield et al., 2017). On the other hand, the short-term tropopause
53 variability is sensitive to various meso- and small-scale atmospheric processes, during
54 which the folding/intrusion events commonly occur. This characteristic of the
55 tropopause change are sometimes directly used to detect the tropopause folds (e.g. Rao
56 et al., 2008; Alexander et al., 2012, and references therein), but are less, if any, directly
57 used to identify stratospheric intrusions. More detailed analysis of the variability of
58 high-resolution tropopause height and of course some other parameters (e.g. 3-

59 dimensional wind), and how the stratospheric air is transported across the tropopause
60 into the troposphere will help us to yield better understanding of the downward
61 stratospheric intrusions (e.g. Sprenger et al., 2003; Leclair de Bellevue et al., 2007; Das
62 et al., 2016).

63 Although photochemical production within the troposphere is the main source of
64 tropospheric ozone, the influence of downward stratospheric intrusions on tropospheric
65 ozone content cannot be ignored (Oltmans and Levy II, 1992; Stevenson et al., 2006).
66 Stratospheric intrusions bring dry ozone-rich air down into the free troposphere (e.g.
67 Stohl et al., 2000; Sørensen and Nielsen, 2001) and sometimes even deep to the surface
68 (e.g. Gerasopoulos et al., 2006; Grant et al., 2008; Jiang et al., 2015; Das et al., 2016;).
69 By now, it is well established that these intrusions of stratospheric origin will
70 significantly influence other trace gases (such as hydroxyl (OH)) in the troposphere
71 (Holton et al., 1995). These influences then will further contribute to the change of
72 radiative balance (Ramaswamy et al., 1992) and play an important role in the radiative
73 forcing of global climate change (Holton et al., 1995). It is true that stratospheric
74 intrusion events occur all over the world and in any seasons. However, they are highly
75 episodic in both vertical and isentropic (horizontal) directions (Chen, 1995). Various
76 dynamical and physical processes have been proposed to be responsible for extra-
77 tropical intrusion events. These mainly include tropopause folds, stratospheric
78 streamers and break-up, cut-off lows (COLs), wave breaking, and mesoscale convective
79 activities and thunderstorms (Stohl et al., 2003).

80 The certain dynamical and chemical characteristics of stratospheric air allow the

81 tracers, such as dry ozone-rich and high PV, to be proper indicators for the intrusions
82 penetrating down into the troposphere. Based on these tracers, various tools are
83 available to detect intrusion events. Balloon-borne ozonesonde sounding is an effective
84 tool to make measurements of ozone with high vertical resolution, but is limited by
85 coverage (He et al., 2011) and temporal resolution. In contrast, the satellite-borne
86 remote sensing instruments, such as Atmospheric Infrared Sounder (AIRS), can provide
87 nearly global coverage of various trace gases but have limitations in vertical and
88 temporal resolution. Another method for studying transport processes is trajectory
89 model, from which the backward trajectories can provide valuable information on the
90 possible sources of the trace gases (e.g. Elbern et al., 1997).

91 By far, large-scale STE has been widely studied and is fairly well understood, but
92 the details of small scale intrusions still need more researches (e.g. Holton et al., 1995).
93 Kumar and Uma (2009) reported that the shortage of direct measurements of vertical
94 winds near the tropopause may be responsible for the lack of fine-scale observations of
95 smaller scale intrusions.

96 Very-High-Frequency (VHF) radars, compared to the tools mentioned above, are
97 capable of continuously monitoring the atmosphere under any weather conditions and
98 detecting tropopause height from backscattered signal with both high temporal and
99 spatial resolution. During the past two decades, VHF radar measurements were
100 commonly used to assist to study the stratospheric intrusions (e.g. Hocking et al., 2007;
101 Das et al., 2016). However, it still remains uncertain in many aspects when using only
102 the VHF radar to identify intrusion events, especially the criteria for the identification.

103 Complicated and changeable atmospheric processes make it difficult to identify the
104 intrusion events by only radar data. The research by Hocking et al., (2007) have
105 achieved a development in this issue and reported that the rapid ascent in RT altitude
106 (>0.2 km/h) can be a valuable diagnostic for possible stratospheric intrusions. They
107 observed the RT height started to ascent just when the stratospheric air intruded across
108 the tropopause layer directly, although the ascent seems to be a recovery from the drop
109 in tropopause height (many cases, not all, including this study). On the other hand, in
110 fact, tropopause drops are more close related to various atmospheric processes such as
111 cutoff low and low/high trough, rather than the corresponding intrusion process itself.
112 Therefore, tropopause ascent is one of the key objects in this study.

113 The central objective of the present study is to discuss the signature of downward
114 cross-tropopause intrusions using both the measurements of tropopause height and
115 vertical wind by the Beijing MST radar. This study is carried out mainly via a detailed
116 case observation during the passage of a COL and other general cases associated with
117 various atmospheric processes. Our discussion mainly focused on the potential of the
118 MST radar data to identify possible intrusion events, which is the main point of this
119 paper. In section 2 the datasets used in this paper are described, section 3 presents
120 detailed results and discussion, and section 4 gives the conclusions.

121

122 2. Dataset

123 2.1. MST radar data and tropopause detection

124 The Beijing MST radar located at Xianghe, China (39.75° N, 116.96° E, 22 m
125 above sea level) is a VHF radar operated at 50 MHz and installed in 2010 based on the
126 first phase of Chinese Meridian Space Weather Monitoring Project (Chinese Meridian
127 Project for short) (Wang, 2010). The radar antenna array consists of 24×24 three-
128 element Yagi to produce an average power aperture product of 3.2×10⁸ Wm² and
129 maximum directive gain of 34.8 dB. It operates radiation pattern with 172 kW peak
130 power and 3.2° half-power beam width. More detailed information of the radar system
131 can be found in Chen et al. (2016). Routine low mode data were used for present study
132 with 0.5 h time resolution and 1 μs coded pulse, which provides 150 m vertical
133 resolution. Details of the low mode setup used in this study are given in Table 1.

134 It has long been known that VHF radar reflectivity is proportional to the mean
135 generalized refractive index gradient M , which is a function of humidity variation and
136 static stability and given by (Ottersten, 1969) as follows

$$137 M = -77.6 \times 10^{-6} (p/T) (d \ln \theta / dz) \\ 138 \cdot \{ 1 + 15500 q / T [1 - (d \ln q / dz) / (2 d \ln \theta / dz)] \} \quad (1)$$

139 where p is the atmospheric pressure (hPa) T is the temperature (K), θ is the potential
140 temperature (K) and q is the specific humidity (gg⁻¹). According to the second and third
141 terms of the equation (1): large humidity variation contributes to the echo from the
142 lower and middle troposphere. From the first term: the radar backscatter power is
143 proportional to the static stability, which in fact is directly proportional to the potential

144 temperature gradient. The tropopause, near which a strong potential temperature
145 gradient exists, will lead to strong radar echoes in vertical incidence, as well as large
146 radar aspect sensitivity (as shown in Figure 1). Radiosonde data used in this paper were
147 received from the GTS1 type digital radiosonde launched from Beijing Meteorological
148 Observatory (39.93 °N, 116.28 °E, station number 54511), which is less than 45 km
149 away from the MST radar site. The black line in Fig. 1 denotes the lapse-rate tropopause
150 (LRT) defined using the temperature lapse rate (World Meteorological Organization
151 (WMO), 1986). Applying the characteristic (enhanced radar echoes due to partial
152 specular reflection) mentioned above, the tropopause can be detected and its height
153 determined by VHF radars (Gage and Green, 1979). It has received widespread
154 application around the world, either in middle latitudes (e.g. Hocking et al., 2007), polar
155 regions (e.g. Alexander et al., 2012), and tropical regions (e.g. Yamamoto et al., 2003;
156 Das et al., 2008). Here, the radar-determined tropopause (RT) height is defined as the
157 height (above 500 hPa) where the maximum vertical gradient of echo power located
158 (shown as the orange circle in Figure 1a). This definition of RT is similar to that in the
159 studies of Alexander et al., [2012] and Ravindrababu et al., [2014].

160 In the present study, the MST radar mainly provides continuous measurements of
161 backscattered echo power, 3-D wind, and RT height with time resolution of 0.5 hour. In
162 addition, the radar aspect sensitivity, expressed as the ratio between vertical (p_v) and
163 oblique (p_o , here used the 15-degree north) beam echo power, is mainly caused by the
164 horizontally stratified anisotropic stable air and thus will be used as potential signature
165 of stratospheric intrusions in the troposphere (e.g. Kim et al., 2001). The backscattered

166 echo power given here is expressed as relative power in decibels (dB). In order to reduce
167 the random noise, the profile of p_v is smoothed by a 3-point running mean in altitude.
168 Note that the data that are heavily contaminated will be eliminated from our datasets.
169 The data of December 2015 and September 2015 are excluded.

170 2.2. AIRS satellite data

171 The AIRS instrument on NASA Aqua/EOS polar orbit satellite is a 2378 channel
172 nadir cross-track scanning infrared spectrometer. It can provide profiles of a number of
173 trace gases, including ozone and CH₄ (Susskind et al., 2003). The footprint of these
174 retrieval data is of 45 km by 45 km and their most sensitive region is in an altitude range
175 of 300-600 hPa. Many studies have shown that these AIRS retrieval constituents are
176 useful indicators for detecting stratospheric intrusions. He et al. [2011] suggested that
177 AIRS can observe the enhanced tropospheric ozone that is of stratospheric origin.
178 Xiong et al. [2013] reported that AIRS is capable of observing abnormal depletion in
179 CH₄ in the troposphere during intrusions. AIRS offers good latitude-longitude coverage.
180 Here we use version 6 of the AIRS Level-3 ozone and methane retrieval products.

181 2.3. Meteorological reanalysis

182 European Centre for Medium-Range Weather Forecasts (ECMWF) reanalysis
183 ERA-interim data are also used. After November 2000 the data are based on the
184 T511L60 version available with a 6-h temporal resolution and $3^\circ \times 3^\circ - 0.125^\circ \times$
185 0.125° latitude-longitude grid (Dee et al., 2011). The dataset from 15 isentropic and
186 37 pressure levels interpolated into $0.5^\circ \times 0.5^\circ$ grid are applied for present study.

187 2.4. HYSPLIT model

188 Backward (forward) trajectories in given starting locations are capable to
189 reproduce the sources (destinations) of the air parcel that will allow us to examine the
190 intrusions of stratospheric origin in the troposphere (e.g. Elbern et al., 1997). The
191 Hybrid Single Particle Lagrangian Integrated Trajectory model (HYSPLIT) developed
192 by the National Oceanic and Atmospheric Administration (NOAA)'s Air Resource
193 Laboratory (ARL) (Rolph, 2003; Stein et al., 2016) is applied to calculate the backward
194 and forward trajectories. The calculation method of the model is a hybrid between the
195 Lagrangian approach and the Eulerian methodology. In this paper, Global Data
196 Assimilation System (GDAS) datasets are adopted for driving the HYSPLIT.
197

198 3. Results and discussion

199 3.1. Meteorological synoptic situation

200 On the morning of 29 November 2014, a 500-hPa trough developed on the western
201 side of Lake Baikal (Western Siberia). The trough moved southeastward and extended
202 equatorward and its southern tip separated from the westerlies in the afternoon of 30
203 November 2014 (Fig. 2b), forming a COL near the radar site as shown by the closed
204 geopotential contour. The black stars in Figure 1 and other figures indicate the location
205 of the radar site. On the following days, the COL system moved northeastward
206 gradually (Fig. 2b) and finally stayed over eastern Russia near Sakhalin Island until it
207 reconnected and merged to the westerly flow. 315 K isentropic PV patterns have shown
208 the coarse resolution features of intrusions from the polar reservoir across the
209 tropopause into the midlatitude troposphere. The PV streamer curved and rolled up
210 cyclonically along the western flank of the COL (Fig. 2b).

211 Fig. 3 shows the time series of hourly surface meteorological parameters over the
212 Beijing station. The data are obtained from the Chinese National Meteorology
213 Information Center and is less than 50 km from the MST radar site. As the dry-cold air
214 invasion accompanied with the COL travelled deeply into the planetary boundary layer,
215 it brought severe weather to the surface, including a rapid decrease in temperature and
216 humidity, and rapid increase in surface wind and sea level pressure. The humidity
217 decreased from ~85 to 12 percent within less than 8 hours. It is well established that the
218 polar-type COLs have strong potential to trigger deep convection (Price and Vaughan,
219 1993). To examine the potential convection, maps of high quality Climate Data Record

220 (CDR) of daily Outgoing Longwave Radiation (OLR) are displayed in Fig. 4. During
221 the development of the COL, a local region with abnormal low OLR value was clearly
222 observed near the radar site on 29 November (Fig. 4b). The Satellite-observed cloud
223 top temperature also showed the low values corresponding to the low OLR (figure not
224 shown), indicating that convection may be generated near radar side on 29 November.
225 Please note that we did not observe such low value either in OLR (Fig.4c, d) or in cloud
226 top temperature near the radar side on 30 November and 1 December. The time for all
227 the observations in this paper is shown in Universal Time (UTC) which is eight hours
228 behind Beijing standard time (LT=UTC+8).

229 **3.2. MST radar observations**

230 Radar echo power, horizontal wind vector, vertical wind, and radar aspect
231 sensitivity are plotted in Figure 5 as function of height and time during the passage of
232 the COL. Time variation of RT (black line) and LRT (black crosses) heights are also
233 displayed. The RT height first experienced a rapid descent, and then increased rapidly,
234 forming a deep V-shaped structure of ~4 km depth. The vertical velocity of the RT
235 height variation (both the rapid descent and ascent branches) reaches up to 0.28 km/h.
236 The rapid RT variation in altitude is in fact the response of the tropopause fold below
237 the jet stream, which will be well represented in Fig. 8a. Rapid variation in RT height
238 remained a region with low echo power (marked by R on Fig. 5a) and low aspect
239 sensitivity (marked by R' on Fig. 5d) where they should be normally high value within
240 the 'normal' tropopause layer. Unlike the RT height, the radiosonde LRT altitudes are
241 nearly constant during the COL passage. In normal conditions, RT agrees well with the

242 LRT altitude, such as indicated by Fig. 6a. However, large differences, of order of 2.5
243 km (as shown in Fig. 6b at 12 UTC 30 November), are observed between LRT and RT
244 in altitude during the passage of the COL as expected. It is the difference in definition
245 that contribute most to the large differences, especially under the tropopause fold
246 conditions (e.g. Yamamoto et al., 2003 and Fukao et al., 2003). It is worth noting that,
247 in Fig.6b, although there is no clear reversion in the radiosonde temperature profile
248 within the height of RT, the RT height exactly corresponds well to the reversion of
249 zonal and meridional wind and potential temperature gradient. Such differences
250 between RT and LRT heights can commonly be observed, especially during extreme
251 synoptic situations such as cyclone (e.g. Alexander et al., 2012).

252 The most important observation in this detailed case experiment is the strong
253 downdrafts (hereinafter inferred to as main downdrafts) observed immediately
254 preceding the rapid RT ascent (Fig.5c). The radar echo power sharply weakened (dotted
255 rectangle in Fig.5a) and the wind direction changed rapidly (Fig.5b, change from
256 dominant southerly wind to dominant northerly jet) within the height region of the main
257 downdrafts. As mentioned previously, abnormal low value in OLR and cloud top
258 temperature indicates the possible occurrence of convective activity on 29 November,
259 but nothing special appeared on 30 November near radar site. Consequently, we
260 preliminarily consider that the main downdrafts occurred near 07 UT 30 November
261 might not be produced directly by convective activity. Here, the accurate origin of the
262 main downdrafts will not be discussed in detail, and it is also beyond the scope of
263 present study.

264 The research by Hocking et al. (2007) has suggested that the rapid ascent in RT
265 height ($>0.2 \text{ km h}^{-1}$) can be a valuable predictor for the occurrence of stratospheric
266 intrusions. Here in this paper, the main downdrafts preceding the rapid RT ascent
267 observed by the Beijing MST radar are thus suspected to be an important feature or
268 response of some form of vertical stratospheric intrusions. Firstly, as the tropopause
269 descends (folded downward), it will displace stratospheric air into the troposphere (e.g.
270 Hoskins et al., 1985). Secondly, the main downdrafts will act as an effective way to
271 weaken the tropopause by means of continuously impinging on the tropopause, through
272 which the stratospheric air is permitted to penetrate down into the free troposphere (e.g.
273 Hirschberg and Fritsch, 1993; Kumar, 2006). In addition, after the main downdrafts,
274 the observed region near the upper troposphere with strong backscatter echoes (marked
275 by Q) and especially with abnormal high aspect sensitivity (marked by Q') may also be
276 a weak signature of the possible intrusions. In normal conditions, they are usually low
277 in value in the upper-troposphere (such as the region marked by P and P'). As we
278 mentioned before, the large value in radar aspect sensitivity is mainly caused by
279 reflection from stable atmospheric layer, such as the tropopause or lower-stratosphere.
280 When stable stratospheric air intrudes into the troposphere and without mixing with the
281 surrounding air mass, the intrusions in the free troposphere will be reflected as
282 abnormal large aspect sensitivity. Further direct evidence of the relevant intrusions in
283 dynamical and chemical aspects will be demonstrated in next section, using satellite
284 AIRS and global reanalysis data.

285 3.3. Associated stratospheric intrusions

286 Due to the sensitivity of the AIRS retrieved ozone and CH₄ is between 300-600
287 hPa. Fig. 7 shows the 500 hPa distribution of AIRS observed ozone and CH₄, along
288 with the AIRS tropopause contour (defined based on the temperature lapse-rate). The
289 ozone distribution maps (left panels of Fig. 7) clearly show a large area with enhanced
290 tropospheric ozone (>80 ppbv) near the radar site during the passage of the COL.
291 Moreover, severe CH₄ depletion (<1840 ppbv) was also observed (right panels in Fig.
292 7). These features of the ozone enhancement, CH₄ depletion, and the corresponding low
293 tropopause altitude clearly support the evidence of vertical downward cross-tropopause
294 stratospheric intrusions on 30 November.

295 The vertical cross-section of ECMWF PV and specific humidity at 1800 UT 30
296 November 2014 and the daily AIRS ozone on 30 November 2014, along a constant
297 latitude 40° N, is shown in Fig. 8. The corresponding vertical structure of the
298 stratospheric intrusions (dry ozone-rich and high PV along with low tropopause) over
299 regions near radar side is clearly seen. The specific humidity tracer displays less distinct
300 structure as compared with the other two tracers (similar as that shown by Vérémes et
301 al., 2016). The cross-section of PV in Fig. 8a have demonstrated relatively finer-scale
302 structure of the stratospheric PV intrusions (below the jet stream), which penetrated
303 down deeply into ~650 hPa (~3.6 km).

304 3.4. Trajectory model analysis

305 Figure 9 shows 30h backward trajectories ending at the radar site at 18 UT 29
306 November (left panel) and at 18 UT 30 November (right panel). As expected, the air
307 masses parcel transported eastward horizontally before the occurrence of main

308 downdrafts (Fig. 9a). Whereas after the downdrafts, the trajectories clearly show
309 downward intrusions originated from the western side of Lake Baikal. Furthermore, a
310 huge dry intrusion is tracked according to the criterion (based on Lagrangian method)
311 in Raveh-Rubin (2017). Trajectory results further support the evidence of possible
312 stratospheric intrusions that closely related with the main downdrafts.

313 On the other hand, 30-h forward trajectories starting at 00 UT 30 November (left
314 panel) and 00 UT 1 December (right panel) are shown in Fig. 10. It is interesting to note
315 that, from Fig. 10a before the passage of COL, the air parcels at 4 km transport rapidly
316 upward (by more than 4 km within ~23 h) and northeastward to the upper-troposphere
317 of East Siberian. This upward and poleward transportation is associated with a warm
318 conveyor belt (southerly flows dominate) that is located ahead of the COL. It
319 contributes to transporting the tropospheric moist and polluted air (such as aerosol) into
320 the upper-troposphere and even the lower stratosphere (e.g. Stohl et al., 2003; Sandhya
321 et al., 2015). After the downdrafts, forward trajectories in Fig. 10b demonstrate that the
322 dry intrusion air parcels continue to be transported downward and southeastward to the
323 boundary layer or even the surface.

324 3.5. Strong downdrafts preceding rapid tropopause ascent and discussion

325 Figure 11a shows another 20 typical cases of strong downdrafts preceding rapid
326 RT ascent for the period March 2012 and Jan. 2015 (shown placed end-to-end), the
327 LRT height (plotted in crosses) and the vertical velocity of the RT (plotted in orange
328 line) is also plotted. These cases (marked by black rectangular boxes and labeled as S1,
329 S2, S3..., and S20) are identified based on the following criteria: 1) the amplitude of

330 the RT ascent should exceed 0.6 km (four range gates), 2) vertical velocities of the RT
331 ascent excess 0.1 km/h, 3) the downdrafts occurred preceding the RT ascent should >0.5
332 m/s, and the height region of the downdrafts should pass through the RT layer. The
333 criteria are put forward mainly to avoid the influence of the RT spikes. Figure 11b
334 shows the backward trajectories for the selected 9 cases. Results show clear evidence
335 of downward intrusions corresponding to the associated strong downdrafts. Their
336 sources are mainly from West Siberia (western side of Lake Baikal), except for the case
337 Tr5. Moreover, according to AIRS daily 500 hPa ozone distribution, most of the cases
338 in Figure 11a (except for the cases S14, S15, S16, S17, S20) were associated with
339 significant ozone enhancement, indicating intrusions of stratospheric origin (as shown
340 in Supplementary figure S1). It is important to note that the RT excursion velocity of
341 all the cases is not all above 0.2 km/h and some are lower than this value (e.g. cases
342 S16 and S18). However, some form of stratospheric intrusions was exactly observed in
343 such cases from both the trajectory and satellite results. Therefore, the threshold of
344 vertical velocity of the RT ascent is set at 0.1 km/h, rather than 0.2 km/h (Hocking et
345 al., 2007). Large differences between RT and LRT are also interesting to be noted on
346 some occasions when the RT changes rapidly (such as the occasion near 14 March
347 2012).

348 According to the meteorological chart, the synoptic situation of those cases
349 identified in Fig. 11a are introduced. The cases S1, S2, S8, S9, S10, and S11 seem to
350 have a close relationship with COL development; cases S3, S4, S5, S6, S7, S17, S18,
351 and S19 seem associated with low or high trough systems (at 500 hPa). The remaining

352 cases seem not associated with any significant synoptic development. However, in
353 terms of the distribution of isentropic PV (generally at 315K in winter and 330K in
354 summer), we found that the remaining cases S12, S13, S14, S15, S16, and S20 appear
355 to be associated with some form of stratospheric streamers and their break-up within
356 the previous 48h (not shown). Some cases (e.g. S1 and S2) that appear close on the
357 same day were probably caused by the same system. The characteristics of the 20 cases,
358 including background synoptic condition, vertical velocity of the RT ascent, and 500
359 hPa ozone enhancement, have been summarized in Table 2.

360 In the light of present understanding, the strong downdrafts preceding the rapid
361 RT ascent can serve as an important diagnostic for intrusion events, during various
362 synoptic processes in any season. This characteristic will be of great use and play an
363 important role in routine identification of stratospheric intrusions. Considering the
364 duration of such downdrafts, a higher time resolution of radar observations will be more
365 helpful. Present study has shown the duration of the majority downdrafts is generally
366 within 1.5-3 hours. We consider, therefore, that the radar resolution should be best
367 within 1h.

368 Although Hocking et al. (2007) have reported that the rapid tropopause ascent
369 (>0.2 km/h) alone can be a useful diagnostic for potential intrusion events. However,
370 using only the information of RT heights might lead to non-negligible errors, as
371 mentioned above in introduction and according to the observations in Fig. 11.
372 Especially on occasions when the RT ascent is between 0.1-0.2 km/h but the
373 corresponding true intrusions were observed, all such intrusion events will be neglected

374 (maybe ~ 2 per month, refer to Fig. 12a). Whereas on some occasions when the RT
375 ascent exceeds 0.2 km/h, but without observing true intrusion events (e.g. He et al.,
376 2011), these events will be misdiagnosed (maybe ~ 13 per month, refer to Fig. 12b). In
377 this sense, using the unique MST radar observations of both the RT height variability
378 and the vertical wind as complementary signature for identifying possible intrusion
379 events is very meaningful.

380 Figure 12 shows four years (2012-2015) of the events with rapid RT ascent (gray
381 bands), and the events with strong downdrafts just preceding the rapid RT ascent (black
382 bands). The identification criteria of such strong downdrafts are similar to that
383 mentioned above and the events are classified according to different value of vertical
384 velocity of the ascent. Among all the events with ascent velocity between 0.1-0.2 km/
385 h, about one-quarter (approximate 2 per month, Fig. 12a) were observed with strong
386 downdrafts preceding them. Whereas, as for the events with the ascent velocity >0.2
387 km/h, the proportion is about a half (approximate 10 per month, Fig. 12b). Here,
388 according to the results above, the occurrence of the strong downdrafts just preceding
389 the rapid RT ascent (black bands in Fig. 12) to a large degree represents the occurrence
390 of possible intrusions. In this way, Fig. 12 indicates that the occurrence of possible
391 intrusions exhibit distinct seasonal variations, with a maximum in winter and spring
392 minimum in summer. This is because the meso- and small-scale atmospheric processes,
393 such as cold air outbreaks, thunderstorms, and convective activities, are more active in
394 winter and spring. They are important sources for downward stratospheric intrusions.

395

396 **4. Conclusions**

397 Detailed case analysis of the cross-tropopause stratospheric intrusions was carried
398 out during a COL. Global reanalysis, satellite data, and HYSPLIT trajectories all
399 showed consistent evidences of dry ozone-rich, high PV, and depleted CH₄ air that have
400 penetrated downward into the free troposphere. The key signature of the stratospheric
401 intrusions in the Beijing MST radar observations is the strong downdrafts just preceding
402 rapid RT ascent. The radar echo power decreased rapidly within the region of strong
403 downdrafts, after which abnormal high aspect sensitivity was recorded in troposphere.
404 Such high aspect sensitivity is served as another potential clue for the intrusions of
405 stratospheric origin.

406 Based on the criteria mentioned in section 3.5, other 20 typical cases of strong
407 downdrafts preceding the rapid RT ascent between March 2012 and January 2015 were
408 presented. These events occurred during different synoptic processes in different
409 seasons. Yet, most of the cases (15 of them) are associated with some form of intrusions
410 observed by combination of AIRS-retrieved ozone and the HYSPLIT trajectory model.
411 Our results show that the radar-derived tropopause height and vertical winds are strong
412 complementary indicators to be used to infer the occurrence of the intrusions of
413 stratospheric origin. This will be of great use and play an important role for the routine
414 identification or prediction of intrusion events. However, the actual origin of the
415 observed downdrafts preceding the rapid RT ascent is not addressed in this paper.
416 Further combination observational experiments need to be conducted, especially
417 combined using ozonesonde soundings, to quantitative analyze the effectiveness of

418 present identification criteria for possible intrusions.

S18	2014/05/02	Low/high trough	0.1-0.2 km/h	Enhanced
S19	2014/05/02	Low/high trough	>0.2 km/h	Enhanced
S20	2015/01/03	PV streamer	>0.2 km/h	None

612 **Table 2.** Characteristics of the 20 cases shown in Fig. 11a.

613

614 **Figures**

615

616 **Figure 1.** Example of the vertical height profiles of (a) the relative radar echo power
 617 (black line, smoothed by a 3-point running mean) along with its gradient variation
 618 (orange line), (b) the aspect sensitivity (black line, expressed as the ratio between the
 619 vertical echo power and oblique echo power) along with its gradient variation (orange
 620 line), observed on 12 UT 29 November 2014. The vertical profiles of simultaneous
 621 radiosonde observed temperature and potential temperature gradient are shown in plots
 622 (c) and (d). The black horizontal line denotes the LRT height derived from the
 623 radiosonde temperature profile. The orange circle indicates the RT height derived from
 624 the profile of the radar backscattered echo power.

625

626 **Figure 2.** ECMWF derived isentropic PV map on 315 K surface (shaded above 2 pvu,
 627 $1 \text{ PVU} = 10^{-6} \text{ m}^2 \text{ K kg}^{-1} \text{ s}^{-1}$) and geopotential height (contoured every 50 m in solid line)
 628 along with the wind vector (arrow) at 500 hPa ($\sim 5.5 \text{ km a.s.l.}$) on (a) 18 UTC 30
 629 November 2014, (b) 12 UTC 1 December 2014. The black star shows the location of
 630 Xianghe.

631

632 **Figure 3.** Time series of surface (~1.2 m above the surface) hourly meteorological

633 measurements of (a) sea level pressure, (b) temperature, (c) relative humidity, (d)

634 horizontal wind, and (e) meridional wind during the period 24 November-6 December

635 2014, observed over the Beijing station (39.4° N, 116.2° E, 31.3 m above sea level).

636

637

638 **Figure 4.** Contour maps of the high quality Climate Data Record (CDR) of the daily
 639 Outgoing Longwave Radiation (OLR), derived from the NOAA high-resolution
 640 infrared radiation sounder (HIRS) on (a) 28 November, (b) 29 November, (c) 30
 641 November, and (d) 1 December 2014. The black star shows the location of Xianghe.

642

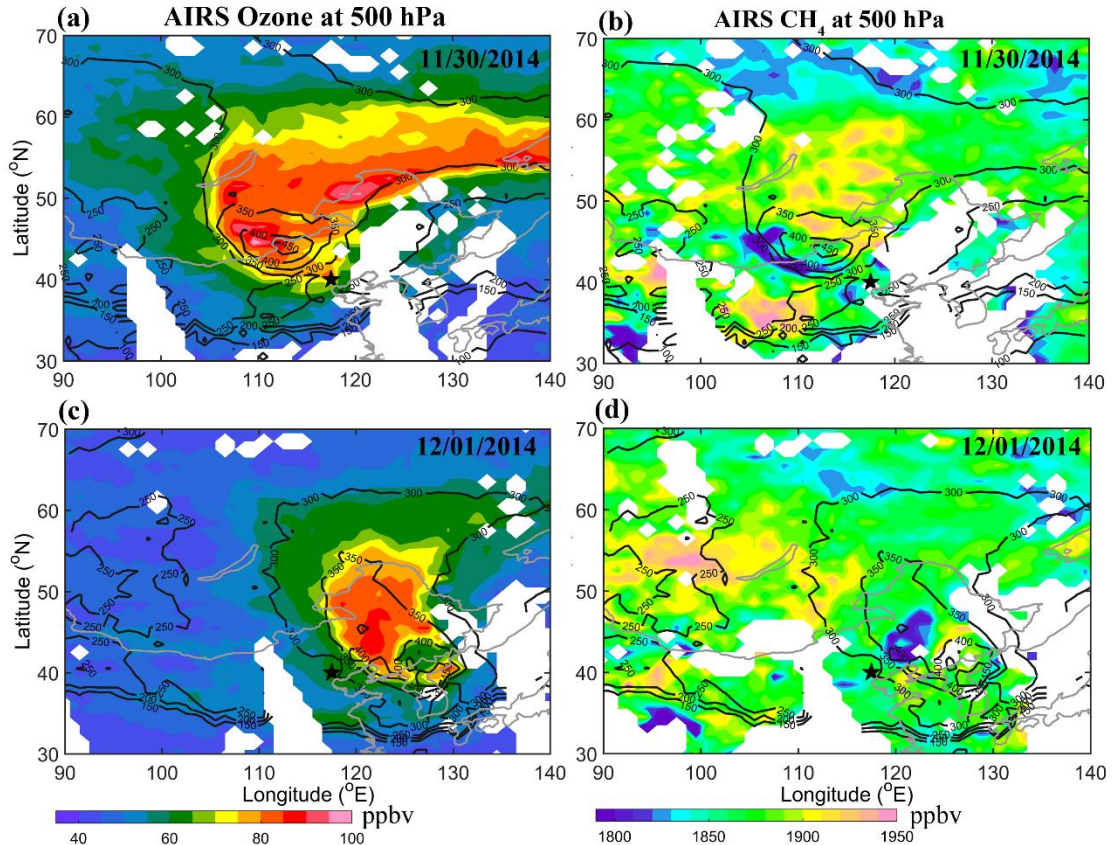

643

644 **Figure 5.** Altitude-time section of (a) the radar backscattered echo power in zenith
 645 direction, (b) the horizontal wind speed along with wind vector, of which the up and
 646 down arrows represent north and south respectively, and left-right is west-east, (c) the
 647 vertical velocity, and (d) the aspect sensitivity, observed by the Beijing MST radar from
 648 29 November to 1 December 2014. The black curve shows the radar-determined
 649 tropopause, as defined in section 2.1. The dotted rectangle highlights the strong
 650 downdrafts immediately preceding the rapid tropopause ascent. The positions of the
 651 LRT tropopause heights, derived from the nearly simultaneous collocated GPS
 652 radiosonde temperature profile, are marked by crosses.

654 **Figure 6.** Vertical profiles of zonal wind, meridional wind, temperature, and potential
 655 temperature gradient derived from the GPS radiosonde measurements, at (a) 0000 UTC
 656 29 November 2014 and (b) 1200 UTC 30 November 2014. The bold arrows on the left
 657 and right side of each panel indicate the radiosonde derived LRT tropopause and radar-
 658 derived tropopause height, respectively.

659

660

661 **Figure 7.** 500 hPa Ozone (left panels) and methane CH₄ (right panels) distribution

662 along with the tropopause height contour, derived from the AIRS satellite observations.

663 The top and bottom plots show the data of 30 November 2014 and 1 December 2014,

664 respectively. According to the Aqua Orbit Tracks (not shown), the time range of the

665 satellite passage is between ~04:00-07:25 on 30 November and between ~03:15-06:35

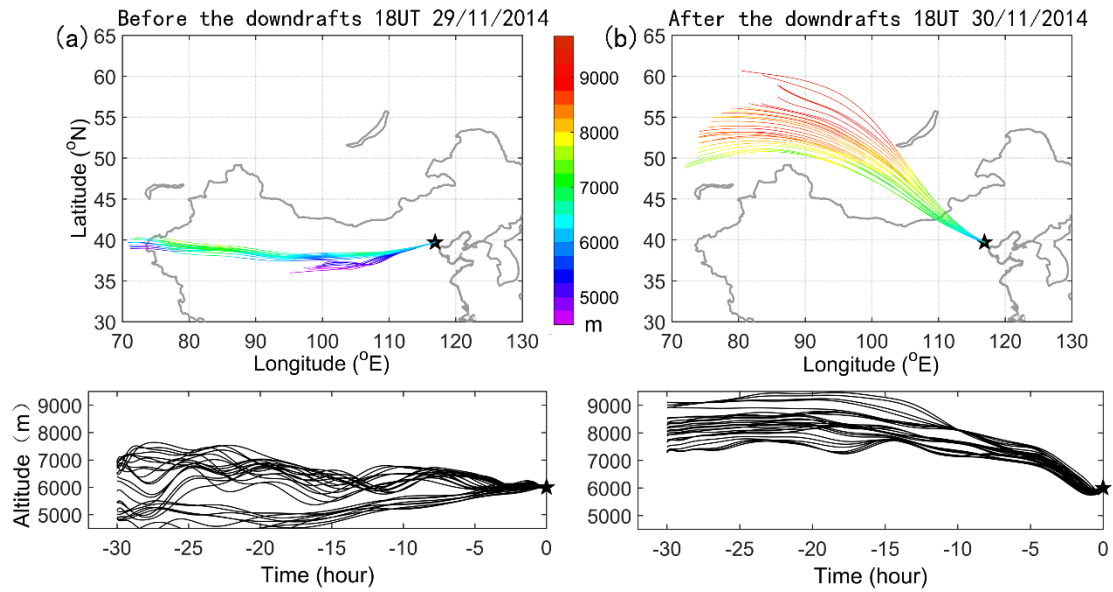

666 on 1 December 2014. The black star indicates the location of Xianghe.

667

668

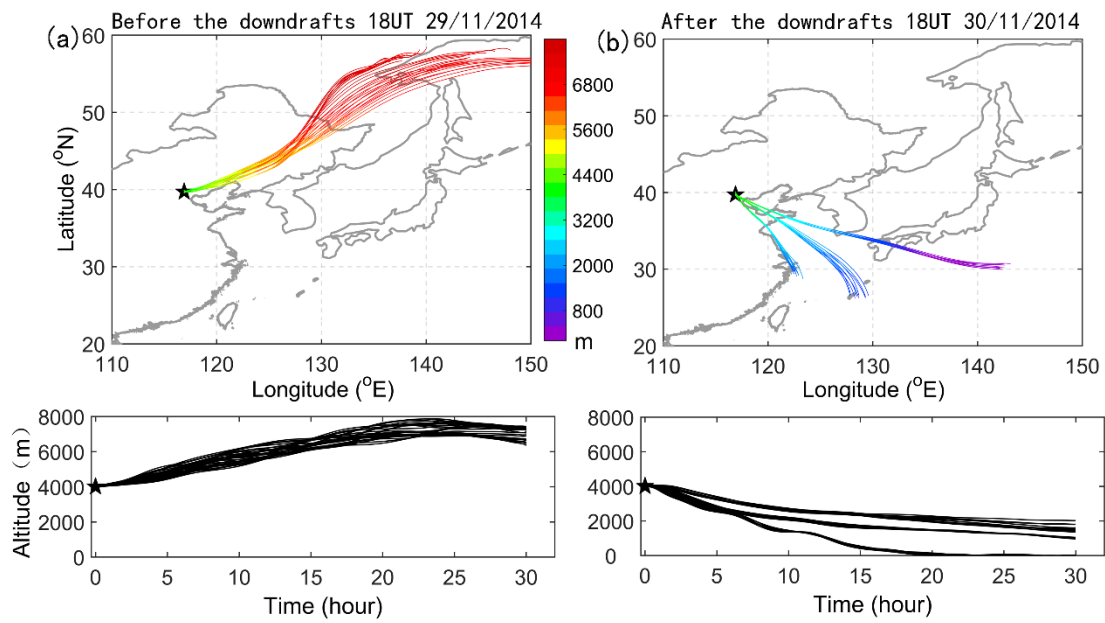

669 **Figure 8.** Longitude-pressure cross section of (a) ECMWF PV (colors, in pvu) along
 670 with horizontal wind contour (thin black line, m/s) at 18 UTC on 30 November 2014,
 671 (b) AIRS ozone mixing ratio (colors, in ppbv) along with tropopause height (black line)
 672 on 30 November 2014, and (c) ECMWF specific humidity (colors, in mg kg^{-1}) at 18
 673 UTC on 30 November 2014, at a constant latitude 40° N (nearest grid point in the
 674 latitude of Xianghe). The bold line in (a) marks the isotropic line of PV at 2 pvu.

675

676 **Figure 9.** Illustration of 30 h three-dimensional backward trajectories ending at
 677 Xianghe at 6000 m using National Oceanic Atmospheric Administration (NOAA)
 678 HYSPLIT model: (a) before the main downdrafts at 18 UTC on 29 November 2014,
 679 and (b) after the main downdrafts at 18 UTC on 30 November 2014. The HYSPLIT
 680 ensemble consists of 27 trajectories. Upper plots show the horizontal projection of the
 681 trajectories, and the lower plots show the corresponding time-height vertical
 682 displacement of the trajectories.

683

684

685 **Figure 10.** Same as Fig.10 but for three-dimensional forward trajectories starting at

686 Xianghe at 4000 m: (a) before the main downdrafts at 00 UTC on 30 November 2014,

687 and (b) after the main downdrafts at 00 UTC on 1 December 2014.

688

689 **Figure 11.** (a) Height-time section of several episodic observations of the radar-derived
 690 vertical wind (colors in m/s) along with RT height (purple bold line) and LRT height
 691 (bold crosses), between March 2012 and Jan. 2015. The corresponding vertical velocity
 692 of the RT (orange line) is plotted in the lower panel of (a), dotted blue line indicates the
 693 value of 0.2 km/h. Dates for the observations are displayed as year/month/day. Black
 694 rectangular boxes represent the cases of strong downdraughts (absolute value ≥ 0.5 m/s)
 695 preceding rapid tropopause ascent (>0.1 km h⁻¹) and are labeled as S1, S2, S3..., S20.

696 Symbol ‘*’ labeled as Tr1-Tr9 indicates the ending point of the corresponding
697 trajectories in Fig.12b. (b) Results of backward trajectories (colors in km) of the typical
698 9 selecting cases from Fig.12a, providing the signature and source of possible
699 stratospheric intrusions.
700

701

702 **Figure 12.** Four years (2012-2015) of radar-determined monthly mean number of rapid

703 tropopause ascent (gray bands) and the corresponding strong downdrafts just preceding

704 the rapid tropopause ascent (black bands). (a) Gray bands: with the ascent by at least

705 0.6 km and the excursion velocity is between 0.1-0.2 km h⁻¹; black bands: except for

706 the criteria of gray bands, strong downdrafts occurred preceding the rapid RT ascent

707 must exceed 0.5 m s^{-1} and pass through the RT layer. (b) Same as (a) but for the
708 occasions when the ascent velocity is larger than 0.2 km h^{-1} . According to the study
709 here, the black bands in the histogram well represent the occurrence of possible
710 stratospheric intrusions.
