13 **Abstract:**

14 The capability of measuring 3-dimensional wind and tropopause structure with
15 relatively high time and vertical resolution makes VHF radar a potentially important
16 tool for studying various processes of the atmosphere. However, at present several open
17 questions remain regarding the use of VHF radar to identify possible stratospheric
18 intrusions. Here the potential detection of stratospheric intrusion events is discussed
19 using the Beijing MST radar located at Xianghe (39.75°N, 116.96°E). During the
20 passage of a cut-off low in late November 2014, a deep V-shaped tropopause structure,
21 and strong downdrafts (>0.8 m/s) immediately preceding the rapid tropopause ascent
22 (>0.2 km/h) were observed. Within the height region of the downdrafts, the stability of

23 the radar tropopause seems to be weakened. Analysis results from global reanalysis and
24 the satellite data, as well as the trajectory model have shown the clear evidence of
25 downward stratospheric intrusions (dry ozone-rich and depleted methane air)
26 associated with the strong downdrafts. Twenty typical cases of such strong downdrafts,
27 occurring during various synoptic processes in different seasons, have been presented
28 and 15 of them are exactly associated with some form of stratospheric intrusions. Four
29 years (2012-2015) of such downdrafts are further discussed. The observations reveal
30 that the strong downdrafts preceding the rapid tropopause ascent can be a valuable
31 diagnostic for monitoring intrusion events, which helps to gain a better understanding
32 of stratospheric intrusions in VHF radar observations.

36

37 1. Introduction

38 The tropopause is a stable transition zone separating the stably stratified
39 stratosphere from the active free troposphere. The stratospheric and tropospheric air are
40 remarkably different in their chemical and dynamical characteristics. The stratosphere
41 is dominantly high in ozone and potential vorticity (PV) content and low in water vapor
42 (WV) and methane (CH₄) concentration, while the troposphere is the contrary (Holton
43 et al., 1995). Consequently, the natural stable tropopause layer, characterized by strong
44 gradients of trace constituents and wind speeds, plays an important role in stratosphere-
45 troposphere exchange (STE) processes. In other words, the layer is a significant barrier
46 for the atmospheric transport between stratosphere and troposphere (Mahlman, 1997).
47 From a long-term point of view, the seasonal variation of the tropopause height
48 determines the seasonal variation of the flux of stratospheric air into the free
49 troposphere (Appenzeller et al., 1996). Under the global climate warming (e.g. the
50 continuing rise in CO₂), the tropopause variation is also a significant factor that must
51 be considered with regards to the recovery of the stratospheric ozone (Butchart et al.,
52 2010; Chipperfield et al., 2017). On the other hand, the short-term tropopause
53 variability is sensitive to various meso- and small-scale atmospheric processes, during
54 which the folding/intrusion events commonly occur. This characteristic of the
55 tropopause change is sometimes directly used to detect the tropopause folds (e.g. Rao
56 et al., 2008; Alexander et al., 2012, and references therein), but is less often, if at all,
57 directly used to identify stratospheric intrusions. More detailed analysis of the
58 variability of high-resolution tropopause height and of course some other parameters

59 (e.g. three-dimensional wind), and how the stratospheric air is transported across the
60 tropopause into the troposphere will help us to obtain a better understanding of the
61 downward stratospheric intrusions (e.g. Sprenger et al., 2003; Leclair de Bellevue et al.,
62 2007; Das et al., 2016).

63 Although photochemical production within the troposphere is the main source of
64 tropospheric ozone, the influence of downward stratospheric intrusions on tropospheric
65 ozone content cannot be ignored (Oltmans and Levy II, 1992; Stevenson et al., 2006).
66 Stratospheric intrusions bring dry ozone-rich air down into the free troposphere (e.g.
67 Stohl et al., 2000; Sørensen and Nielsen, 2001) and sometimes even deep to the surface
68 (e.g. Gerasopoulos et al., 2006; Grant et al., 2008; Jiang et al., 2015; Das et al., 2016;).
69 By now, it is well established that these intrusions of stratospheric origin will
70 significantly influence other trace gases (such as hydroxyl (OH)) in the troposphere
71 (Holton et al., 1995). These influences then will further contribute to the change of
72 radiative balance (Ramaswamy et al., 1992) and play an important role in the radiative
73 forcing of global climate change (Holton et al., 1995). It is true that stratospheric
74 intrusion events occur all over the world and in any season. However, they are highly
75 episodic in both vertical and isentropic (horizontal) directions (Chen, 1995). Various
76 dynamical and physical processes have been proposed to be responsible for extra-
77 tropical intrusion events. These mainly include tropopause folds, stratospheric
78 streamers and break-up, cut-off lows (COLs), wave breaking, and mesoscale convective
79 activities and thunderstorms (Stohl et al., 2003).

80 The certain dynamical and chemical characteristics of stratospheric air allow the

81 tracers, such as dry ozone-rich and high PV, to be proper indicators for the intrusions
82 penetrating down into the troposphere. Based on these tracers, various tools are
83 available to detect intrusion events. Balloon-borne ozonesonde sounding is an effective
84 tool to make measurements of ozone with high vertical resolution, but is limited by
85 coverage (He et al., 2011) and temporal resolution. In contrast, the satellite-borne
86 remote sensing instruments, such as Atmospheric Infrared Sounder (AIRS), can provide
87 nearly global coverage of various trace gases but have limitations in vertical and
88 temporal resolution. Another method for studying transport processes is trajectory
89 model, from which the backward trajectories can provide valuable information on the
90 possible sources of the trace gases (e.g. Elbern et al., 1997).

91 By far, large-scale STE has been widely studied and is fairly well understood, but
92 the details of small scale intrusions still need more research (e.g. Holton et al., 1995).
93 Kumar and Uma (2009) reported that the shortage of direct measurements of vertical
94 winds near the tropopause may be responsible for the lack of fine-scale observations of
95 smaller scale intrusions.

96 Very-High-Frequency (VHF) radars, compared to the tools mentioned above, are
97 capable of continuously monitoring the atmosphere under any weather conditions and
98 detecting tropopause height from backscattered signal with both high temporal and
99 spatial resolution. During the past two decades, VHF radar measurements were
100 commonly used to assist to study the stratospheric intrusions (e.g. Hocking et al., 2007;
101 Das et al., 2016). However, it still remains uncertain in many aspects when using only
102 the VHF radar to identify intrusion events, especially the criteria for the identification.

103 Complicated and changeable atmospheric processes make it difficult to identify the
104 intrusion events by only radar data. Hocking et al., (2007) reported that the rapid ascent
105 in radar-derived tropopause (RT) altitude (>0.2 km/h) can be a valuable diagnostic for
106 possible stratospheric intrusions. Their observation results clearly indicate that almost
107 every occurrence of definite stratospheric intrusion is related to a definite RT ascent
108 (>0.2 km/h, occurred at or just before the intrusion). The reverse is also reasonable, that
109 is almost every occurrence of definite RT ascent is associated with some form of
110 intrusion (Hocking et al., 2007). Please note that we did not mean that the tropopause
111 ascent is the best and most accurate diagnostic that can be used directly for identifying
112 possible intrusions. As motivated by the study of Hocking et al., (2007), tropopause
113 ascent is one of the key objects in this study.

114 Using only the information of RT height variability is, of course, insufficient for
115 quantifying intrusion events accurately by radar data. Therefore, radar measurements
116 of vertical motions are also considered simultaneously to discuss the possible capability
117 of radar measurements for identifying cross-tropopause stratospheric intrusions, which
118 is the main point of this paper. This study is carried out mainly via a detailed case
119 observation during a COL passage and other 20 general cases during various synoptic
120 situations. In section 2 the datasets used in this paper are described, section 3 presents
121 detailed results and discussion, and section 4 gives the conclusions.

122

123 2. Dataset

124 2.1. MST radar data and tropopause detection

125 The Beijing MST radar located at Xianghe, China (39.75° N, 116.96° E, 22 m
126 above sea level) is a VHF radar operated at 50 MHz and installed in 2010 based on the
127 first phase of Chinese Meridian Space Weather Monitoring Project (Chinese Meridian
128 Project for short) (Wang, 2010). The radar antenna array consists of 24×24 three-
129 element Yagi to produce an average power aperture product of $3.2 \times 10^8 \text{ Wm}^2$ and
130 maximum directive gain of 34.8 dB. It operates radiation pattern with 172 kW peak
131 power and 3.2° half-power beam width. More detailed information of the radar system
132 can be found in Chen et al. (2016). Routine low mode data were used for present study
133 with 0.5 h time resolution and 1 μs coded pulse, which provides 150 m vertical
134 resolution. Details of the low mode setup used in this study are given in Table 1.

135 It has long been known that VHF radar reflectivity is proportional to the mean
136 generalized refractive index gradient M , which is a function of humidity variation and
137 static stability and given by Ottersten (1969) as follows

$$138 \quad M = -77.6 \times 10^{-6} (p/T) (d \ln \theta / dz) \\ 139 \quad \cdot \{ 1 + 15500 q / T [1 - (d \ln q / dz) / (2 d \ln \theta / dz)] \} \quad (1)$$

140 where p is the atmospheric pressure (hPa) T is the temperature (K), θ is the potential
141 temperature (K) and q is the specific humidity (gg^{-1}). According to the second and third
142 terms of the equation (1): large humidity variation contributes to the echo from the
143 lower and middle troposphere. From the first term: the radar backscatter power is
144 proportional to the static stability, which in fact is directly proportional to the potential

145 temperature gradient. The tropopause, near which a strong potential temperature
146 gradient exists, will lead to strong radar echoes in vertical incidence, as well as large
147 radar aspect sensitivity (as shown in Figure 1). Radiosonde data used in this paper were
148 received from the GTS1 type digital radiosonde launched from Beijing Meteorological
149 Observatory (39.93 °N, 116.28 °E, station number 54511), which is less than 45 km
150 away from the MST radar site. The black line in Fig. 1 denotes the lapse-rate tropopause
151 (LRT) defined using the temperature lapse rate (World Meteorological Organization
152 (WMO), 1986). Applying the characteristic (enhanced radar echoes due to partial
153 specular reflection) mentioned above, the tropopause can be detected and its height
154 determined by VHF radars (Gage and Green, 1979). It has received widespread
155 application around the world, either in middle latitudes (e.g. Hocking et al., 2007), polar
156 regions (e.g. Alexander et al., 2012), and tropical regions (e.g. Yamamoto et al., 2003;
157 Das et al., 2008). Here, the radar-determined tropopause (RT) height is defined as the
158 height (above 500 hPa) where the maximum vertical gradient of echo power located
159 (shown as the orange circle in Figure 1a). This definition of RT is similar to that in the
160 studies of Alexander et al., [2012] and Ravindrababu et al., [2014].

161 In the present study, the MST radar mainly provides continuous measurements of
162 backscattered echo power, 3-D wind, and RT height with time resolution of 0.5 hour. In
163 addition, the radar aspect sensitivity, expressed as the ratio between vertical (p_v) and
164 oblique (p_o , here used the 15-degree north) beam echo power, is mainly caused by the
165 horizontally stratified anisotropic stable air and thus will be used as potential signature
166 of stratospheric intrusions in the troposphere (e.g. Kim et al., 2001). The backscattered

167 echo power given here is expressed as relative power in decibels (dB). In order to reduce
168 the random noise, the profile of p_v is smoothed by a 3-point running mean in altitude.
169 Note that the data that are heavily contaminated will be eliminated from our datasets.
170 The data of December 2015 and September 2015 are excluded.

171 2.2. AIRS satellite data

172 The AIRS instrument on NASA Aqua/EOS polar orbit satellite is a 2378 channel
173 nadir cross-track scanning infrared spectrometer. It can provide profiles of a number of
174 trace gases, including ozone and CH₄ (Susskind et al., 2003). The footprint of these
175 retrieval data is 45 km by 45 km and their most sensitive region is in an altitude range
176 of 300-600 hPa. Many studies have shown that these AIRS retrieval constituents are
177 useful indicators for detecting stratospheric intrusions. He et al. [2011] suggested that
178 AIRS can observe the enhanced tropospheric ozone that is of stratospheric origin.
179 Xiong et al. [2013] reported that AIRS is capable of observing abnormal depletion in
180 CH₄ in the troposphere during intrusions. AIRS offers good latitude-longitude coverage.
181 Here we use version 6 of the AIRS Level-3 ozone and methane retrieval products.

182 2.3. Meteorological reanalysis

183 European Centre for Medium-Range Weather Forecasts (ECMWF) reanalysis
184 ERA-interim data are also used. After November 2000 the data are based on the
185 T511L60 version available with a 6-h temporal resolution and $3^\circ \times 3^\circ - 0.125^\circ \times$
186 0.125° latitude-longitude grid (Dee et al., 2011). The dataset from 15 isentropic and
187 37 pressure levels interpolated into $0.5^\circ \times 0.5^\circ$ grid are applied for the present study.

188 2.4. HYSPLIT model

189 Backward (forward) trajectories in given starting locations are capable to
190 reproduce the sources (destinations) of the air parcel that will allow us to examine the
191 intrusions of stratospheric origin in the troposphere (e.g. Elbern et al., 1997). The
192 Hybrid Single Particle Lagrangian Integrated Trajectory model (HYSPLIT) developed
193 by the National Oceanic and Atmospheric Administration (NOAA)'s Air Resource
194 Laboratory (ARL) (Rolph, 2003; Stein et al., 2016) is applied to calculate the backward
195 and forward trajectories. The calculation method of the model is a hybrid between the
196 Lagrangian approach and the Eulerian methodology. In this paper, Global Data
197 Assimilation System (GDAS) datasets are adopted for driving the HYSPLIT.
198

199 **3. Results and discussion**

200 3.1. Meteorological synoptic situation

201 On the morning of 29 November 2014, a 500-hPa trough developed on the western
202 site of Lake Baikal (Western Siberia). The trough moved southeastward and extended
203 equatorward and its southern tip separated from the westerlies in the afternoon of 30
204 November 2014 (Fig. 2b), forming a COL near the radar site as shown by the closed
205 geopotential contour. The black stars in Figure 1 and other figures indicate the location
206 of the radar site. On the following days, the COL system moved northeastward
207 gradually (Fig. 2b) and finally stayed over eastern Russia near Sakhalin Island until it
208 reconnected and merged to the westerly flow. 315 K isentropic PV patterns have shown
209 the coarse resolution features of intrusions from the polar reservoir across the
210 tropopause into the midlatitude troposphere. The PV streamer curved and rolled up
211 cyclonically along the western flank of the COL (Fig. 2b).

212 Fig. 3 shows the time series of hourly surface meteorological parameters over the
213 Beijing station. The data are obtained from the Chinese National Meteorology
214 Information Center and is less than 50 km from the MST radar site. As the dry-cold air
215 invasion accompanied with the COL travelled deeply into the planetary boundary layer,
216 it brought severe weather to the surface, including a rapid decrease in temperature and
217 humidity, and rapid increase in surface wind and sea level pressure. The humidity
218 decreased from ~85 to 12 percent within less than 8 hours. It is well established that the
219 polar-type COLs have strong potential to trigger deep convection (Price and Vaughan,
220 1993). To examine the potential convection, maps of high quality Climate Data Record

221 (CDR) of daily Outgoing Longwave Radiation (OLR) (Lee, 2014) are displayed in Fig.
222 4. During the development of the COL, a local region with abnormal low OLR value
223 was clearly observed near the radar site on 29 November (Fig. 4b). The Satellite-
224 observed cloud top temperature also showed the low values corresponding to the low
225 OLR (figure not shown), indicating that convection may be generated near radar site on
226 29 November. Please note that we did not observe such low value either in OLR (Fig.4c,
227 d) or in cloud top temperature near the radar site on 30 November and 1 December. The
228 time for all the observations in this paper is shown in Universal Time (UTC) which is
229 eight hours behind Beijing standard time (LT=UTC+8).

230 **3.2. MST radar observations**

231 Radar echo power, horizontal wind vector, vertical wind, and radar aspect
232 sensitivity are plotted in Figure 5 as function of height and time during the passage of
233 the COL. Time variation of RT (black line) and LRT (black crosses) heights are also
234 displayed. The RT height first experienced a rapid descent, and then increased rapidly,
235 forming a deep V-shaped structure of ~4 km depth. The vertical velocity of the RT
236 height variation (both the rapid descent and ascent branches) reaches up to 0.28 km/h.
237 The rapid RT variation in altitude is in fact the response of the tropopause fold below
238 the jet stream, which will be well represented in Fig. 8a. Rapid variation in RT height
239 created a region with low echo power (marked by R on Fig. 5a) and low aspect
240 sensitivity (marked by R' on Fig. 5d) where normally one would expect to find a high
241 value within the 'normal' tropopause layer. Unlike the RT height, the radiosonde LRT
242 altitudes are nearly constant during the COL passage. In normal conditions, RT agrees

243 well with the LRT altitude, such as indicated by Fig. 6a. However, large differences, of
244 order of 2.5 km (as shown in Fig. 6b at 12 UTC 30 November), are observed between
245 LRT and RT in altitude during the passage of the COL as expected. It is the difference
246 in definition that contribute most to the large differences, especially under the
247 tropopause fold conditions (e.g. Yamamoto et al., 2003 and Fukao et al., 2003). It is
248 worth noting that, in Fig.6b, although there is no clear reversion in the radiosonde
249 temperature profile within the height of RT, the RT height corresponds well to the
250 reversion of zonal and meridional wind and potential temperature gradient. Such
251 differences between RT and LRT heights can commonly be observed, especially during
252 extreme synoptic situations such as cyclones (e.g. Alexander et al., 2012).

253 The most important observation in this detailed case experiment is the strong
254 downdrafts (hereinafter inferred to as main downdrafts) observed immediately
255 preceding the rapid RT ascent (Fig.5c). The radar echo power sharply weakened (dotted
256 rectangle in Fig.5a) and the wind direction changed rapidly (Fig.5b, change from
257 dominant southerly wind to dominant northerly jet) within the height region of the main
258 downdrafts. As mentioned previously, abnormal low value in OLR and cloud top
259 temperature indicates the possible occurrence of convective activity on 29 November,
260 but nothing special appeared on 30 November near radar site. Consequently, we
261 preliminarily consider that the main downdrafts occurred near 07 UT 30 November
262 might not be produced directly by convective activity. Here, the accurate origin of the
263 main downdrafts will not be discussed in detail, and it is also beyond the scope of
264 present study.

265 The research by Hocking et al. (2007) has suggested that the rapid ascent in RT
266 height ($>0.2 \text{ km h}^{-1}$) can be a valuable diagnostic for the occurrence of stratospheric
267 intrusions. Here in this paper, the main downdrafts preceding the rapid RT ascent
268 observed by the Beijing MST radar are thus suspected to be an important feature or
269 response of some form of vertical stratospheric intrusions. Firstly, as the tropopause
270 descends (folded downward), it will displace stratospheric air into the troposphere (e.g.
271 Hoskins et al., 1985). Secondly, the main downdrafts will act as an effective way to
272 weaken the tropopause by means of continuously impinging on the tropopause, through
273 which the stratospheric air is permitted to penetrate down into the free troposphere (e.g.
274 Hirschberg and Fritsch, 1993; Kumar, 2006). In addition, after the main downdrafts,
275 the observed region near the upper troposphere with strong backscatter echoes (marked
276 by Q) and especially with abnormal high aspect sensitivity (marked by Q') may also be
277 a weak signature of the possible intrusions. In normal conditions, they are usually low
278 in value in the upper-troposphere (such as the region marked by P and P'). As we
279 mentioned before, large value in radar aspect sensitivity is caused mainly by reflection
280 from stable atmospheric layer, such as the tropopause or lower-stratosphere. When
281 stable stratospheric air intrudes into the troposphere and without mixing with the
282 surrounding air mass, the intrusions in the free troposphere will be reflected as
283 abnormal large aspect sensitivity. Further direct evidence of the relevant intrusions in
284 dynamical and chemical aspects will be demonstrated in next section, using satellite
285 AIRS and global reanalysis data.

286 3.3. Associated stratospheric intrusions

287 Due to the sensitivity of the AIRS retrieved ozone and CH₄ is between 300-600
288 hPa. Fig. 7 shows the 500 hPa distribution of AIRS observed ozone and CH₄, along
289 with the AIRS tropopause contour (defined based on the temperature lapse-rate). The
290 ozone distribution maps (left panels of Fig. 7) clearly show a large area with enhanced
291 tropospheric ozone (>80 ppbv) near the radar site during the passage of the COL.
292 Moreover, severe CH₄ depletion (<1840 ppbv) was also observed (right panels in Fig.
293 7). These features of the ozone enhancement, CH₄ depletion, and the corresponding low
294 tropopause altitude clearly support the evidence of vertical downward cross-tropopause
295 stratospheric intrusions on 30 November.

296 The vertical cross-section of ECMWF PV and specific humidity at 1800 UT 30
297 November 2014 and the daily AIRS ozone on 30 November 2014, along a constant
298 latitude 40° N, is shown in Fig. 8. Please note that the high-PV and dry air have been
299 observed intruding deep into troposphere of as low as 650 hPa (~3.6 km). Whereas the
300 vertical structure of AIRS ozone has shown that the enhanced ozone intruded into
301 troposphere of ~500 hPa. This difference in vertical scale of intrusion between ozone
302 and PV parameters is most likely due to two reasons: 1) the local high PV value
303 observed near ~600 hPa is not a true stratospheric characterized intrusion but rather
304 adiabatically-produced high PV (e.g. Skerlak et al 2015); 2) the relatively poor vertical
305 resolution of AIRS ozone data may have limited the refined observation of the
306 intrusions. From this figure, however, it is clear that stratospheric air (dry ozone-rich
307 and high PV) intrusions have indeed occurred and were observed (at least intruded
308 downward into ~500 hPa).

309 3.4. Trajectory model analysis

310 Figure 9 shows 30h backward trajectories ending at the radar site at 18 UT 29
311 November (left panel) and at 18 UT 30 November (right panel). As expected, the air
312 mass parcel is transported eastward horizontally before the occurrence of main
313 downdrafts (Fig. 9a). Whereas after the downdrafts, the trajectories clearly show
314 downward intrusions originated from the western site of Lake Baikal. Furthermore, a
315 huge dry intrusion is tracked according to the criterion (based on Lagrangian method)
316 in Raveh-Rubin (2017). Trajectory results further support the evidence of downward
317 intrusions that are closely related with the main downdrafts.

318 On the other hand, 30-h forward trajectories starting at 00 UT 30 November (left
319 panel) and 00 UT 1 December (right panel) are shown in Fig. 10. It is interesting to note
320 that, from Fig. 10a before the passage of COL, the air parcels at 4 km are transported
321 rapidly upward (by more than 4 km within ~23 h) and northeastward to the upper-
322 troposphere of East Siberian. This upward and poleward transport is associated with a
323 warm conveyor belt (southerly flows dominate) that is located ahead of the COL. It
324 contributes to transporting the tropospheric moist and polluted air (such as aerosol) into
325 the upper-troposphere and even the lower stratosphere (e.g. Stohl et al., 2003; Sandhya
326 et al., 2015). After the downdrafts, forward trajectories in Fig. 10b demonstrate that the
327 dry intrusion air parcels continue to be transported downward and southeastward to the
328 boundary layer or even the surface.

329 3.5. Strong downdrafts preceding rapid tropopause ascent and discussion

330 Figure 11a shows another 20 typical cases of strong downdrafts preceding rapid

331 RT ascent for the period March 2012 and Jan. 2015 (shown placed end-to-end), the
332 LRT height (plotted in crosses) and the vertical velocity of the RT (plotted in orange
333 line) is also plotted. These cases (marked by black rectangular boxes and labeled as S1,
334 S2, S3..., and S20) are identified based on the following criteria: 1) the amplitude of
335 the RT ascent should exceed 0.6 km (four range gates), 2) vertical velocities of the RT
336 ascent excess 0.1 km/h, 3) the downdrafts occurred preceding the RT ascent should >0.5
337 m/s, and the height region of the downdrafts should pass through the RT layer. The
338 criteria are put forward mainly to avoid the influence of the RT spikes. Figure 11b
339 shows the backward trajectories for the selected 9 cases. Results show clear evidence
340 of downward intrusions corresponding to the associated strong downdrafts. Their
341 sources are mainly from West Siberia (western site of Lake Baikal), except for the case
342 Tr5. Moreover, according to AIRS daily 500 hPa ozone distribution, most of the cases
343 in Figure 11a (except for the cases S14, S15, S16, S17, S20) were associated with
344 significant ozone enhancement, indicating intrusions of stratospheric origin (as shown
345 in Supplementary figure S1). It is important to note that the RT excursion velocity of
346 all the cases is not all above 0.2 km/h and some are lower than this value (e.g. cases
347 S16 and S18). However, some form of stratospheric intrusions was exactly observed in
348 such cases from both the trajectory and satellite results. Therefore, the threshold of
349 vertical velocity of the RT ascent is set at 0.1 km/h, rather than 0.2 km/h (Hocking et
350 al., 2007). Large differences between RT and LRT are also interesting to be noted on
351 some occasions when the RT changes rapidly (such as the occasion near 14 March
352 2012).

353 According to the meteorological chart, the synoptic situation of those cases
354 identified in Fig. 11a are introduced. The cases S1, S2, S8, S9, S10, and S11 seem to
355 have a close relationship with COL development; cases S3, S4, S5, S6, S7, S17, S18,
356 and S19 seem associated with low or high trough systems (at 500 hPa). The remaining
357 cases seem not associated with any significant synoptic development. However, in
358 terms of the distribution of isentropic PV (generally at 315K in winter and 330K in
359 summer), we found that the remaining cases S12, S13, S14, S15, S16, and S20 appear
360 to be associated with some form of stratospheric streamers and their break-up within
361 the previous 48h (not shown). Some cases (e.g. S1 and S2) that appear close on the
362 same day were probably caused by the same system. The characteristics of the 20 cases,
363 including background synoptic condition, vertical velocity of the RT ascent, and 500
364 hPa ozone enhancement, have been summarized in Table 2.

365 In the light of present understanding, the strong downdrafts preceding the rapid
366 RT ascent can serve as an important diagnostic for intrusion events, during various
367 synoptic processes in any season. This characteristic will be of great use and play an
368 important role in routine identification of stratospheric intrusions. Considering the
369 duration of such downdrafts, a higher time resolution of radar observations will be more
370 helpful. The present study has shown the duration of most downdrafts is generally
371 within 1.5-3 hours. We consider, therefore, that the radar resolution should be best
372 within 1h.

373 Although Hocking et al. (2007) have reported that the rapid tropopause ascent
374 (>0.2 km/h) alone can be a useful diagnostic for potential intrusion events. However,

375 using only the information of RT heights might lead to non-negligible errors, as
376 mentioned above in introduction and according to the observations in Fig. 11.
377 Especially on occasions when the RT ascent is between 0.1-0.2 km/h but the
378 corresponding true intrusions were observed, all such intrusion events will be neglected
379 (maybe ~2 per month, refer to Fig. 12a). Whereas on some occasions when the RT
380 ascent exceeds 0.2 km/h, but without observing true intrusion events (e.g. He et al.,
381 2011), these events will be misdiagnosed (maybe ~13 per month, refer to Fig. 12b). In
382 this sense, using the unique MST radar observations of both the RT height variability
383 and the vertical wind as complementary signature for identifying possible intrusion
384 events is very meaningful.

385 Figure 12 shows four years (2012-2015) of the events with rapid RT ascent (gray
386 bands), and the events with strong downdrafts just preceding the rapid RT ascent (black
387 bands). The identification criteria of such strong downdrafts are similar to that
388 mentioned above and the events are classified according to different value of vertical
389 velocity of the ascent. Among all the events with ascent velocity between 0.1-0.2 km/
390 h, about one-quarter (approximate 2 per month, Fig. 12a) were observed with strong
391 downdrafts preceding them. Whereas, as for the events with the ascent velocity >0.2
392 km/h, the proportion is about a half (approximate 10 per month, Fig. 12b). Here,
393 according to the results above, the occurrence of the strong downdrafts just preceding
394 the rapid RT ascent (black bands in Fig. 12) to a large degree represents the occurrence
395 of possible intrusions. In this way, Fig. 12 indicates that the occurrence of possible
396 intrusions exhibit distinct seasonal variations, with a maximum in winter and spring

397 minimum in summer. This is because the meso- and small-scale atmospheric processes,
398 such as cold air outbreaks, thunderstorms, and convective activities, are more active in
399 winter and spring. They are important sources for downward stratospheric intrusions.
400

401 **4. Conclusions**

402 Detailed case analysis of the cross-tropopause stratospheric intrusions was carried
403 out during a COL. Global reanalysis, satellite data, and HYSPLIT trajectories all
404 showed consistent evidences of dry ozone-rich, high PV, and depleted CH₄ air that have
405 penetrated downward into the free troposphere. The key signature of the stratospheric
406 intrusions in the Beijing MST radar observations is the strong downdrafts just preceding
407 rapid RT ascent. The radar echo power decreased rapidly within the region of strong
408 downdrafts, after which abnormal high aspect sensitivity was recorded in troposphere.
409 Such high aspect sensitivity served as another potential clue for the intrusions of
410 stratospheric origin.

411 Based on the criteria mentioned in section 3.5, other 20 typical cases of strong
412 downdrafts preceding the rapid RT ascent between March 2012 and January 2015 were
413 presented. These events occurred during different synoptic processes in different
414 seasons. Yet, most of the cases (15 of them) are associated with some form of intrusions
415 observed by combination of AIRS-retrieved ozone and the HYSPLIT trajectory model.
416 Our results show that the radar-derived tropopause height and vertical winds are strong
417 complementary indicators to be used to infer the occurrence of the intrusions of
418 stratospheric origin. This will be of great use and play an important role for the routine
419 identification or prediction of intrusion events. However, the actual origin of the
420 observed downdrafts preceding the rapid RT ascent is not addressed in this paper.
421 Further combination observational experiments need to be conducted, especially
422 combined using ozonesonde soundings, to quantitative analyze the effectiveness of

423 present identification criteria for possible intrusions.

424

425

426 **Acknowledgment**

427 The authors really appreciate Prof Shira Raveh-Rubin for reading and commenting the
428 manuscript. This work is funded by National Natural Science Foundation of China
429 (NSFC grants No. 41722404 and 41474132). The authors would like to thank the staff
430 of Chinese Meridian Space Weather Monitoring Project (CMSWMP) for their support
431 in conducting the experiment. The authors sincerely acknowledge the ECMWF, NASA,
432 and NOAA Air Resources Laboratory (ARL) for providing global reanalysis, satellite
433 data, and HYSPLIT transport model, respectively. The interpolated OLR data are
434 provided by the NOAA/OAR/ESRL PSD, Boulder, Colorado, USA, from their Web site
435 at <https://www.esrl.noaa.gov/psd/>. The MST radar data are available at Data Centre for
436 Meridian Space Weather Monitoring Project (<http://159.226.22.74/>). The radiosonde
437 data is available from <http://weather.uwyo.edu/upperair/sounding.html>.

S17	2014/01/04	Low/high trough	>0.2 km/h	None
S18	2014/05/02	Low/high trough	0.1-0.2 km/h	Enhanced
S19	2014/05/02	Low/high trough	>0.2 km/h	Enhanced
S20	2015/01/03	PV streamer	>0.2 km/h	None

614 **Table 2.** Characteristics of the 20 cases shown in Fig. 11a.

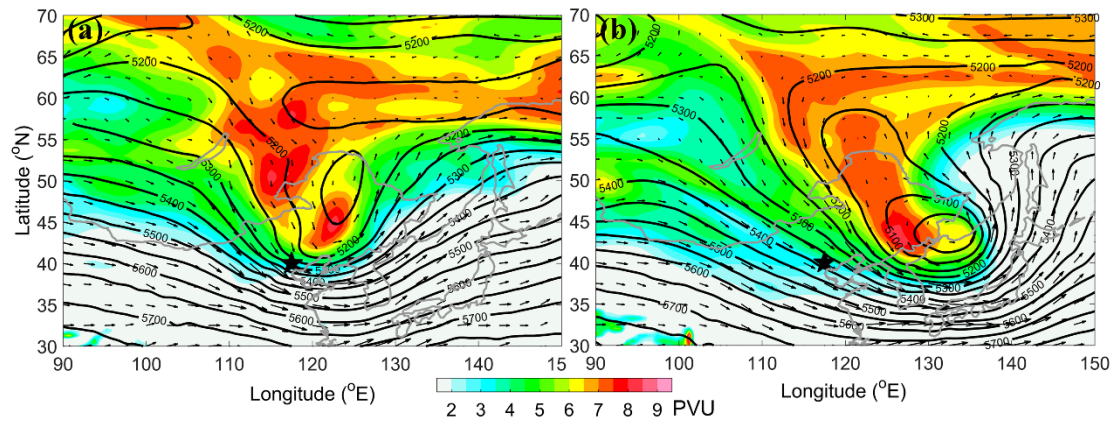

615

616 **Figures**

617

618 **Figure 1.** Example of the vertical height profiles of (a) the relative radar echo power
 619 (black line, smoothed by a 3-point running mean) along with its gradient variation
 620 (orange line), (b) the aspect sensitivity (black line, expressed as the ratio between the
 621 vertical echo power and oblique echo power) along with its gradient variation (orange
 622 line), observed on 12 UT 29 November 2014. The vertical profiles of simultaneous
 623 radiosonde observed temperature and potential temperature gradient are shown in plots
 624 (c) and (d). The black horizontal line denotes the LRT height derived from the
 625 radiosonde temperature profile. The orange circle indicates the RT height derived from
 626 the profile of the radar backscattered echo power.

627

628 **Figure 2.** ECMWF derived isentropic PV map on 315 K surface (shaded above 2 pvu,
 629 $1 \text{ PVU} = 10^{-6} \text{ m}^2 \text{ K kg}^{-1} \text{ s}^{-1}$) and geopotential height (contoured every 50 m in solid line)
 630 along with the wind vector (arrow) at 500 hPa ($\sim 5.5 \text{ km a.s.l.}$) on (a) 18 UTC 30
 631 November 2014, (b) 12 UTC 1 December 2014. The black star shows the location of
 632 Xianghe.

633

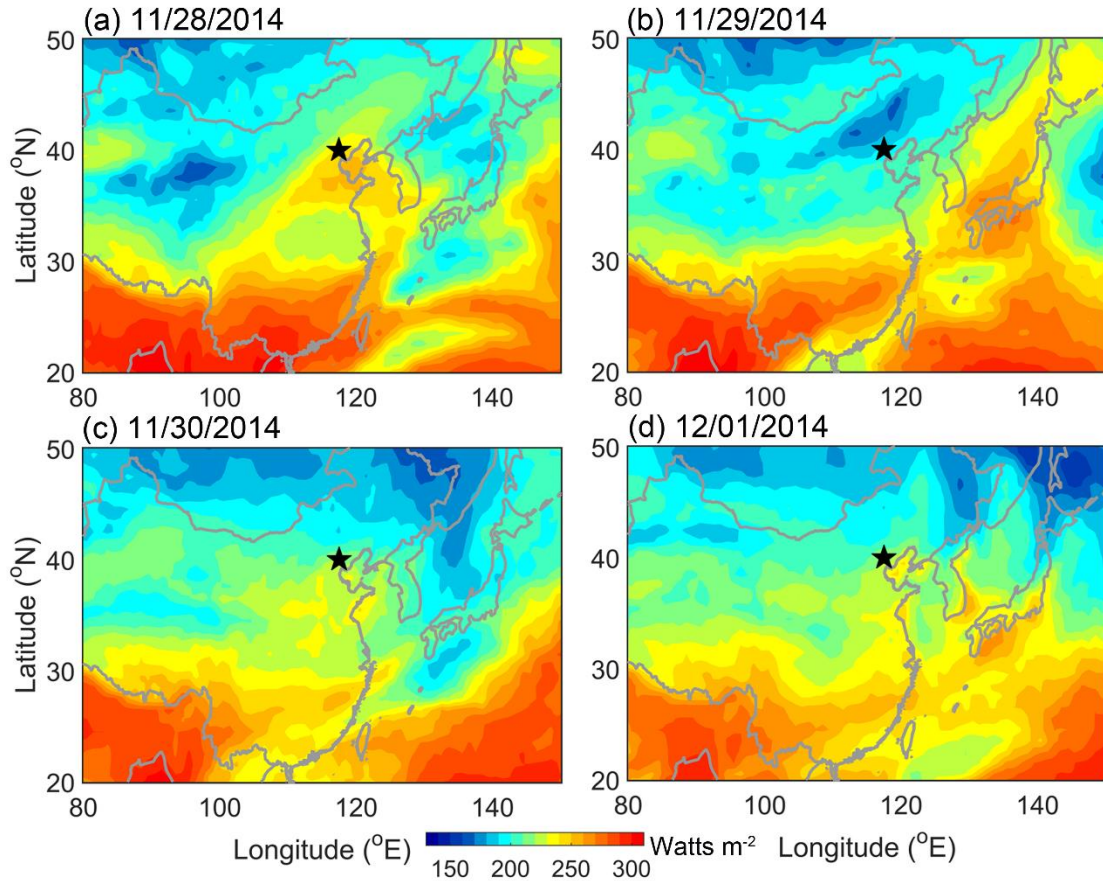

634 **Figure 3.** Time series of surface (~1.2 m above the surface) hourly meteorological

635 measurements of (a) sea level pressure, (b) temperature, (c) relative humidity, (d)

636 horizontal wind, and (e) meridional wind during the period 24 November-6 December

637 2014, observed over the Beijing station (39.4° N, 116.2° E, 31.3 m above sea level).

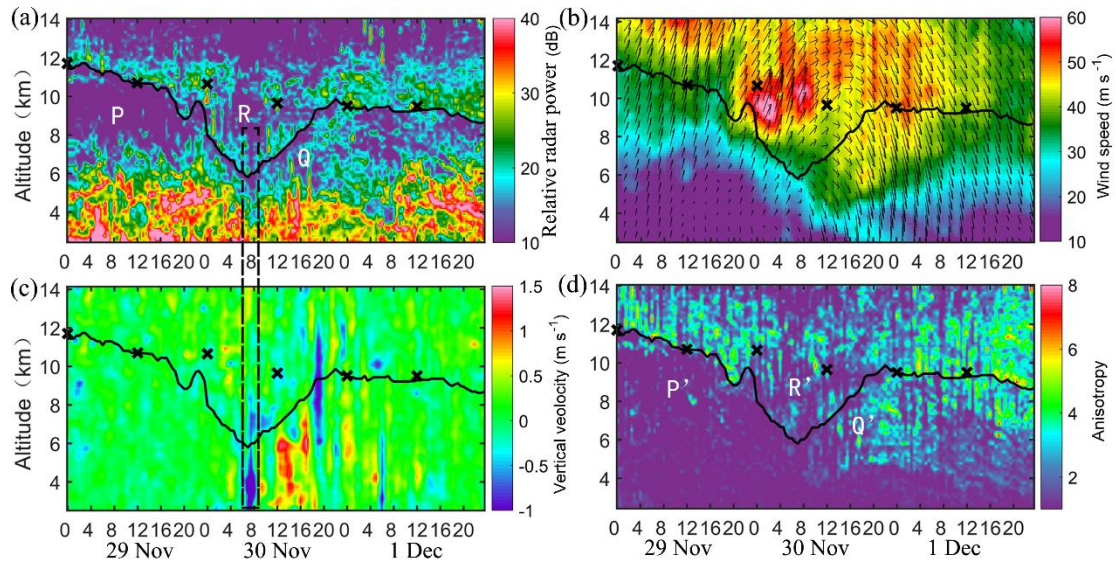

638

639

640 **Figure 4.** Contour maps of the high quality Climate Data Record (CDR) of the daily
 641 Outgoing Longwave Radiation (OLR), derived from the NOAA high-resolution
 642 infrared radiation sounder (HIRS) on (a) 28 November, (b) 29 November, (c) 30
 643 November, and (d) 1 December 2014. The black star shows the location of Xianghe.

644

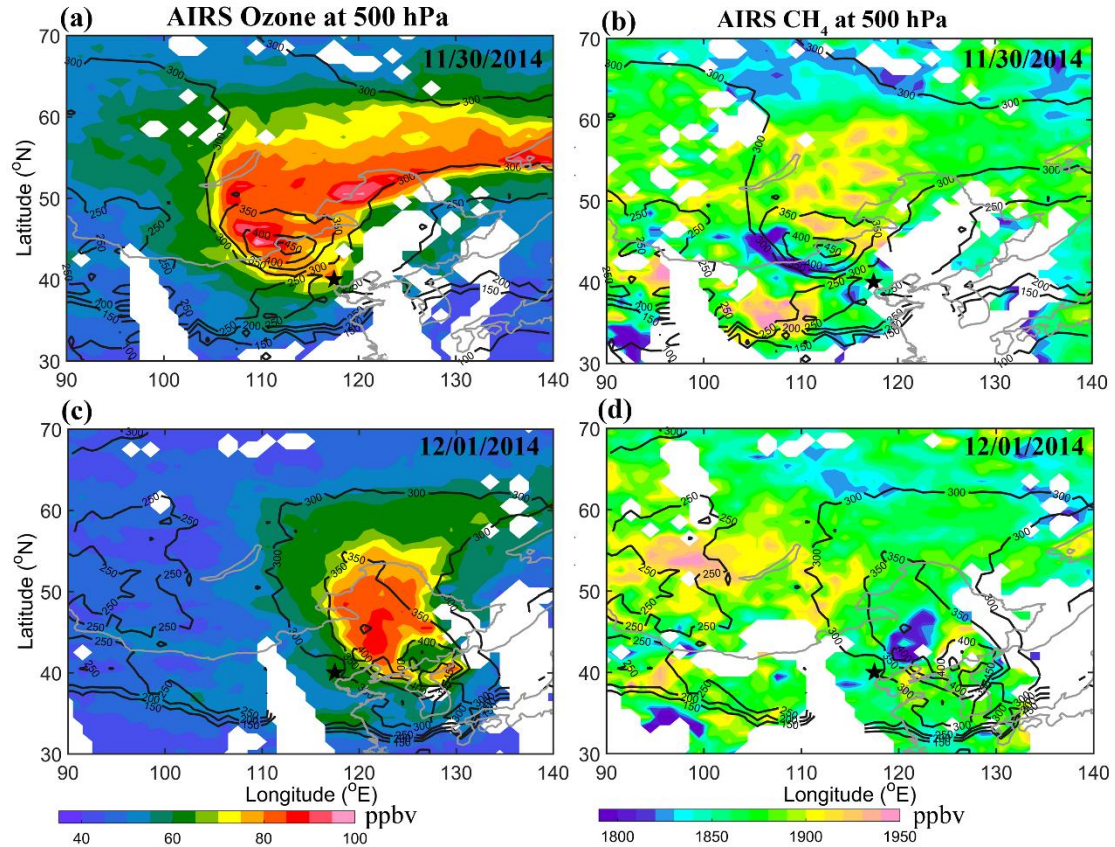

645

646 **Figure 5.** Altitude-time section of (a) the radar backscattered echo power in zenith
 647 direction, (b) the horizontal wind speed along with wind vector, of which the up and
 648 down arrows represent north and south respectively, and left-right is west-east, (c) the
 649 vertical velocity, and (d) the aspect sensitivity, observed by the Beijing MST radar from
 650 29 November to 1 December 2014. The black curve shows the radar-determined
 651 tropopause, as defined in section 2.1. The dotted rectangle highlights the strong
 652 downdrafts immediately preceding the rapid tropopause ascent. The positions of the
 653 LRT tropopause heights, derived from the nearly simultaneous collocated GPS
 654 radiosonde temperature profile, are marked by crosses.

656 **Figure 6.** Vertical profiles of zonal wind, meridional wind, temperature, and potential
 657 temperature gradient derived from the GPS radiosonde measurements, at (a) 0000 UTC
 658 29 November 2014 and (b) 1200 UTC 30 November 2014. The bold arrows on the left
 659 and right site of each panel indicate the radiosonde derived LRT tropopause and radar-
 660 derived tropopause height, respectively.

661

662

663 **Figure 7.** 500 hPa Ozone (left panels) and methane CH₄ (right panels) distribution

664 along with the tropopause height contour, derived from the AIRS satellite observations.

665 The top and bottom plots show the data of 30 November 2014 and 1 December 2014,

666 respectively. According to the Aqua Orbit Tracks (not shown), the time range of the

667 satellite passage is between ~04:00-07:25 on 30 November and between ~03:15-06:35

668 on 1 December 2014. The black star indicates the location of Xianghe.

669

670

671 **Figure 8.** Longitude-pressure cross section of (a) ECMWF PV (colors, in pvu) along
 672 with horizontal wind contour (thin black line, m/s) at 18 UTC on 30 November 2014,
 673 (b) AIRS ozone mixing ratio (colors, in ppbv) along with tropopause height (black line)
 674 on 30 November 2014, and (c) ECMWF specific humidity (colors, in mg kg⁻¹) at 18
 675 UTC on 30 November 2014, at a constant latitude 40° N (nearest grid point in the
 676 latitude of Xianghe). The bold line in (a) marks the isotropic line of PV at 2 pvu.

677

678 **Figure 9.** Illustration of 30 h three-dimensional backward trajectories ending at
 679 Xianghe at 6000 m using National Oceanic Atmospheric Administration (NOAA)
 680 HYSPLIT model: (a) before the main downdrafts at 18 UTC on 29 November 2014,
 681 and (b) after the main downdrafts at 18 UTC on 30 November 2014. The HYSPLIT
 682 ensemble consists of 27 trajectories. Upper plots show the horizontal projection of the
 683 trajectories, and the lower plots show the corresponding time-height vertical
 684 displacement of the trajectories.

685

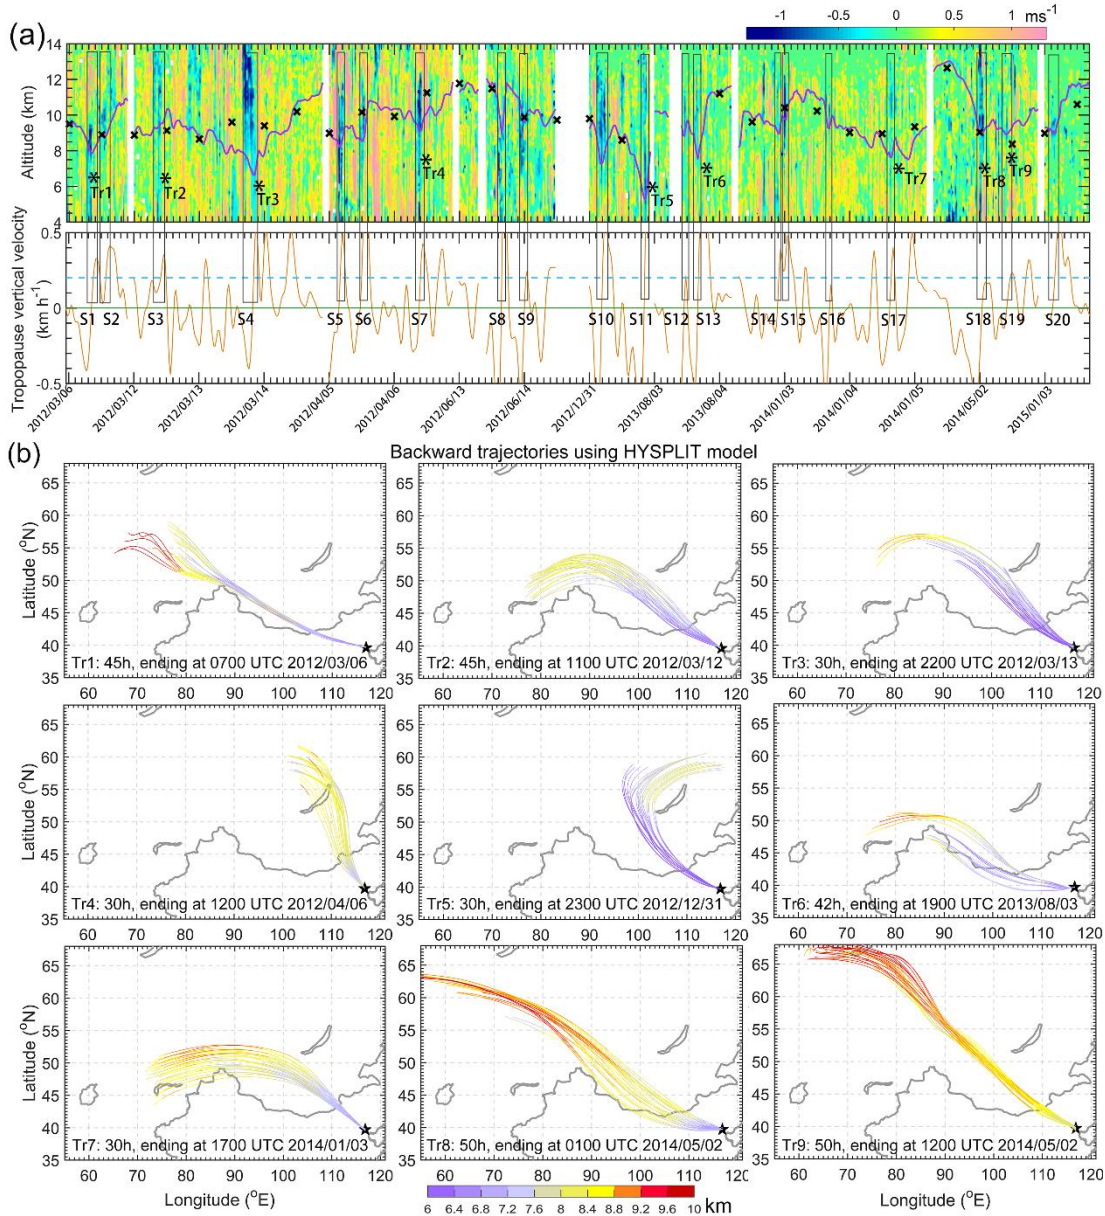

686

687 **Figure 10.** Same as Fig.10 but for three-dimensional forward trajectories starting at

688 Xianghe at 4000 m: (a) before the main downdrafts at 00 UTC on 30 November 2014,

689 and (b) after the main downdrafts at 00 UTC on 1 December 2014.

690

691 **Figure 11.** (a) Height-time section of several episodic observations of the radar-derived
 692 vertical wind (colors in m/s) along with RT height (purple bold line) and LRT height
 693 (bold crosses), between March 2012 and Jan. 2015. The corresponding vertical velocity
 694 of the RT (orange line) is plotted in the lower panel of (a), dotted blue line indicates the
 695 value of 0.2 km/h. Dates for the observations are displayed as year/month/day. Black
 696 rectangular boxes represent the cases of strong downdraughts (absolute value ≥ 0.5 m/s)
 697 preceding rapid tropopause ascent (>0.1 km h⁻¹) and are labeled as S1, S2, S3..., S20.

698 Symbol ‘*’ labeled as Tr1-Tr9 indicates the ending point of the corresponding
699 trajectories in Fig.12b. (b) Results of backward trajectories (colors in km) of the typical
700 9 selecting cases from Fig.12a, providing the signature and source of possible
701 stratospheric intrusions.
702

703

704 **Figure 12.** Four years (2012-2015) of radar-determined monthly mean number of rapid

705 tropopause ascent (gray bands) and the corresponding strong downdrafts just preceding

706 the rapid tropopause ascent (black bands). (a) Gray bands: with the ascent by at least

707 0.6 km and the excursion velocity is between 0.1-0.2 km h⁻¹; black bands: except for

708 the criteria of gray bands, strong downdrafts occurred preceding the rapid RT ascent

709 must exceed 0.5 m s^{-1} and pass through the RT layer. (b) Same as (a) but for the
710 occasions when the ascent velocity is larger than 0.2 km h^{-1} . According to the study
711 here, the black bands in the histogram well represent the occurrence of possible
712 stratospheric intrusions.
