**Abstract.** We study the interaction of solar wind protons with the Earth's quasi-parallel bow shock using a hybrid-Vlasov simulation. We employ the high-fidelity global hybrid model Vlasiator to include effects due to bow shock curvature, tenuous upstream populations, and foreshock waves. We investigate the local uncertainty of the position of the quasi-parallel bow shock as a function of several plasma properties, and find that for a significant portion of time, the local bow shock position is challenging to define. Our results support the notion of upstream structures causing patchwork reconstruction of the quasi-parallel shock front in a non-uniform manner. We propose a novel method for spacecraft data to be used to analyze this quasi-parallel reformation.

We combine our hybrid-Vlasov results with test-particle studies and show that shock non-locality appears to have little direct efficient on particle injection. We show that proton energization, which is required for injection, takes place throughout a larger shock transition zone. Non-local energization of particles is found regardless of the instantaneous non-locality of the shock front. Distortion of magnetic fields in front of and at the shock is shown to have a significant effect on proton injection.

We additionally show that the density of suprathermal reflected particles upstream of the shock may not be a useful metric for the probability of injection at the shock, as foreshock dynamics and particle trapping appear to have a greater effect on energetic particle accumulation at a given position in space. Our results have significant implications for statistical and spacecraft studies of the shock injection problem.

## 1 Introduction

Collisionless plasma shocks are an ubiquitous source of plasma acceleration, common within stellar, planetary, and interplanetary environments. They have been studied in great detail at the Earth's bow shock. In regions of shock geometry where the angle  $\theta_{Bn}$  between the shock-normal direction  $\hat{n}$  and the upstream interplanetary magnetic field (IMF) direction  $\mathbf{B}$  is small ( $\lesssim 45^\circ$ ), the shock is considered quasi-parallel (see, e.g., Burgess et al., 2005). In this region, if the shock is a strong fast-mode

supercritical shock, a fraction of thermal incident ions are reflected, streaming away from the shock along the magnetic field lines, forming the foreshock region (Fairfield, 1969; Eastwood et al., 2005). The streaming energized particles excite instabilities such as a right-hand ion-ion beam instability, building a wave field of ultra-low frequency (ULF) waves (Hoppe et al., 1981) with periods around  $\sim 30$ s, which further interact with the particles themselves and are convected toward the bow shock. As the waves are convected with the solar wind flow, they appear mostly left-handed in the spacecraft frame. The incident ULF waves can experience nonlinear steepening, possibly forming shocklets (Hada et al., 1987; Wilson III, 2016) or short large amplitude magnetic structures (SLAMS; Schwartz et al., 1992; Burgess, 1995; Lucek et al., 2008), eventually causing patchwork reformation of the bow shock (Scholer and Terasawa, 1990; Thomas and Winske, 1990; Schwartz and Burgess, 1991; Burgess, 1995) as incoming structures proceed to build a new shock front periodically (Burgess, 1989). In this study, we limit our analysis to ion scales and assume the reformation of the quasi-parallel bow shock to happen on temporal and spatial scales similar to those of steepened ULF waves and associated transient structures.

An important open question for space physics and particle acceleration is the shock injection problem (see, e.g., Zank et al., 2001), or how exactly thermal particles are reflected at a super-critical quasi-parallel shock. Injection from a thermal population is a necessary step in efficient diffusive shock acceleration (DSA; Axford et al., 1977; Blandford and Ostriker, 1978; Bell, 1978; Krymsky et al., 1979), which is a major source of energetic particles throughout the universe. The injection problem has been studied extensively during the past decades with, amongst others, observations (Sckopke et al., 1983; Thomsen et al., 1983; Gosling et al., 1989; Johlander et al., 2016), analytical work (Schwartz et al., 1983; Malkov et al., 2016), test-particle modeling (Gedalin, 2001; Battarbee et al., 2011; Gedalin, 2016), and particle-in-cell simulations (Caprioli et al., 2015; Liseykina et al., 2015; Sundberg et al., 2016; Hao et al., 2016; Caprioli et al., 2017). Significant historical work using 1-D or 2-D local hybrid simulations can be found in, e.g., Burgess (1989); Scholer (1990) and Kucharek and Scholer (1991). Previous studies have suggested three methods for injection: Specular reflection (Gosling et al., 1982), shock drift acceleration (SDA; Giacalone, 1992; Lever et al., 2001; Burgess, 1987) and associated shock surfing (Lever et al., 2001), and thermal leakage from the downstream (Ellison, 1981; Edmiston et al., 1982; Lyu and Kan, 1990; Malkov, 1998). All these methods were derived from assumptions of macroscopic, planar, and stationary shock fronts and are thus limited, but an important first step towards understanding the concept. Magnetic mirroring as described through quasi-linear theory and conservation of the first adiabatic invariant is usually excluded, as changes to magnetic fields may occur on scales much smaller and faster than those of ion gyromotion.

In this paper, we investigate the complex structure and non-locality of the Earth's quasi-parallel bow shock as well as the injection problem both through hybrid-Vlasov simulations and test-particle runs. In section 2 we present our hybrid-Vlasov simulations. In section 3 we present results from two different hybrid-Vlasov datasets. In section 4 we introduce our test-particle simulation method, and in section 5 we present results of test-particle injection and energization. Section 6 presents analysis and discussion on our findings, and we present our conclusions in section 7.

Throughout this study, we use the following terminology:

- An *injected* particle has interacted with the bow shock and returned to the upstream. This may also be called *reflection*. During this process, particles are energized.

- A *transmitted* particle has passed through the bow shock to the downstream. The particle may or may not be energized during this process.
- *Energization* is when during a single shock encounter, a particle gains energy so that it is no longer part of the incident plasma thermal distribution.
- *Acceleration* is when injected particles continue to gain energy through continuous and/or repeated shock interactions, such as DSA. This takes place over longer temporal and spatial scales, and is outside the scope of this study.
- *Non-locality* of the quasi-parallel bow shock is a measure of the disagreement between different measurements of where the bow shock is locally estimated to be. This could also be referred to as the uncertainty of the shock position.
- The *shock-normal direction*  $\hat{n}$  is normal to the local, reforming shock front. This direction is highly variable.
- The *bow-normal direction*  $\hat{n}'$  is the normal direction for a parabola, estimating the global shape of the shock front. This direction is very stable.
- The *shock-normal angle*  $\theta_{Bn}$  is the angle between the upstream magnetic field and the shock-normal direction. The shock-normal direction or a vector antiparallel to it is chosen in order to constrain the value to  $\theta_{Bn} \in [0^\circ, 90^\circ]$ . Due to fluctuations of both the upstream field and the local shock front, this angle is very unpredictable.
- The *bow-normal angle*  $\theta_{Bn'}$  is the angle between the upstream magnetic field and the bow-normal direction. Like  $\theta_{Bn}$ , it is usually limited to  $\theta_{Bn'} \in [0^\circ, 90^\circ]$ , but in regions of significant magnetic field deformation, is allowed to have values  $> 90^\circ$ . This measure allows analysis of shock interaction due to upstream magnetic field fluctuations while smoothing out the local reformation effects of the quasi-parallel shock front.

## 2 Vlasiator simulation

In modeling the Earth's bow shock, we employ Vlasiator (von Althaus et al., 2014; Pfau-Kempf, 2016; Palmroth et al., 2018), a hybrid-Vlasov code designed to simulate the Earth's magnetosphere and the surrounding space environment. Vlasiator models kinetic proton-scale plasma physics by calculating the evolution of the proton distribution function on a cartesian 3-dimensional velocity grid within each cell of a cartesian spatial grid. In the presented runs, the spatial simulation domain is 2-dimensional. Modeling distribution functions directly instead of using a particle-in-cell method allows for accurate analysis of even the tenuous portions of non-thermal populations in the foreshock, and gives us a realistic model of foreshock and bow shock evolution. The noise-free distribution function formalism further allows using the magnetic field  $\mathbf{B}$  and electric field  $\mathbf{E}$  values as input to test-particle studies without a need for low-pass filtering.

Vlasiator models ions as distribution functions, solving the Vlasov equation for the ion (proton) distribution with electrons modeled as a cold massless charge-neutralizing fluid. Closure is provided via Ohm's law, including the Hall term. We assume that effects due to the electron pressure gradient can be neglected. Vlasiator is capable of modeling a number of ion kinetic

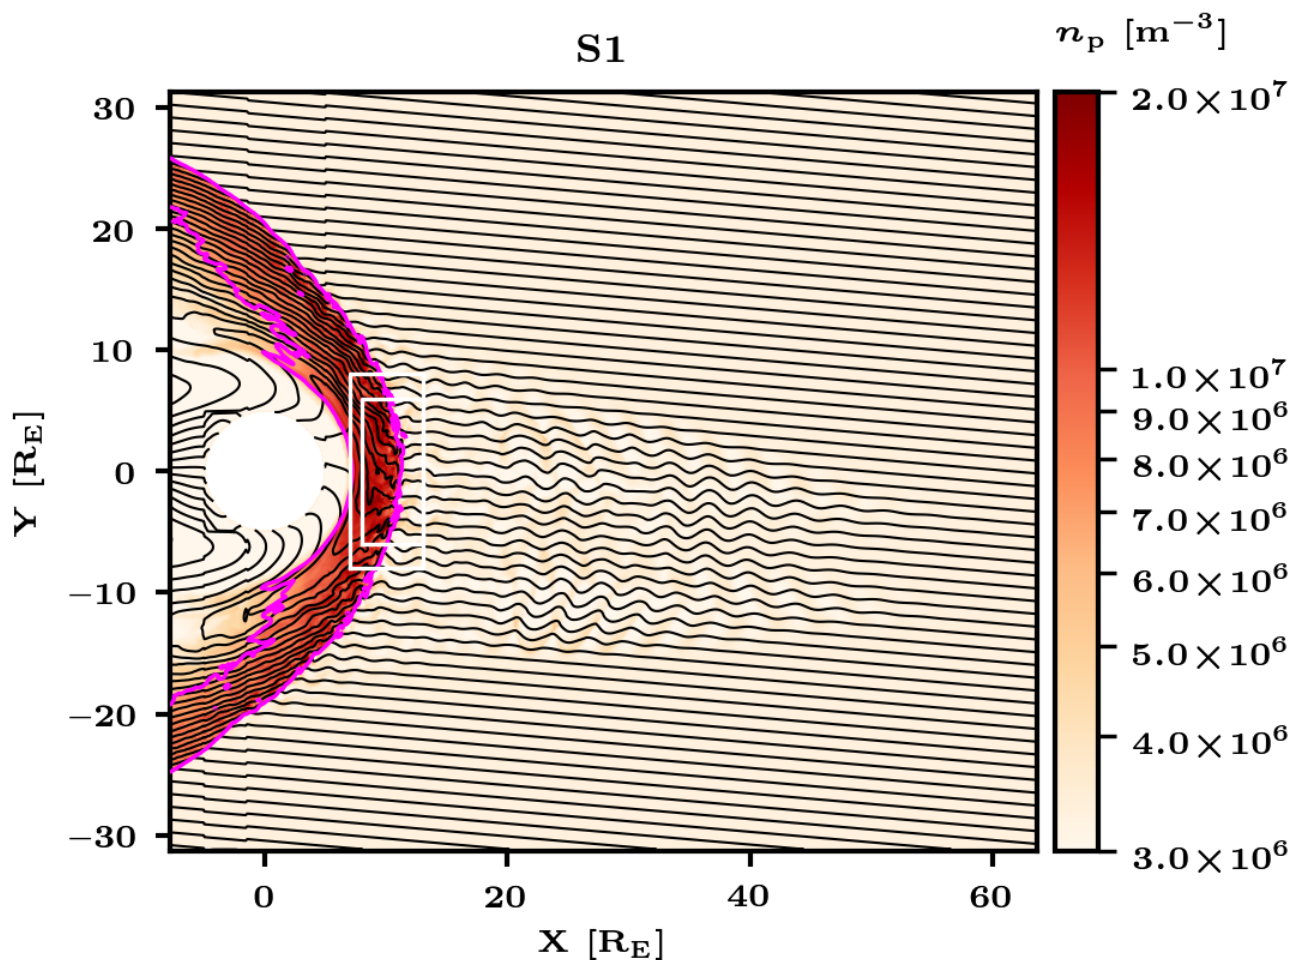

effects even without resolving ion kinetic scales spatially (Pfau-Kempf et al., 2018), and has been used for a number of interesting foreshock and bow shock studies (Palmroth et al., 2015; Pfau-Kempf et al., 2016; Turc et al., 2018; Blanco-Cano et al., 2018)

90 In this paper, we use two datasets (simulations S1 and S2) modeling two different bow shock strengths and interplanetary magnetic field intensities. Results from these simulations have previously been published in Palmroth et al. (2015) and Turc et al. (2018). They are ecliptic plane ( $x-y$ ) 2D–3V simulations (2D in the spatial domain, 3D in the velocity domain) parametrized using the GSE coordinate system with no tilt for the Earth’s dipole. The  $x$ -coordinate is along the Earth-Sun axis, the  $z$ -coordinate is aligned with the Earth’s magnetic axis, and the  $y$ -coordinate completes the right-handed system. We  
95 save variables such as field values and distribution function moments every 0.5 s. The simulation extent is  $2000 \times 1750$  spatial cells, covering the ranges  $x \in [-7.7, 63.6] r_E$  and  $y \in [-31.3, 31.3] r_E$  where  $r_E = 6371$  km is the Earth radius. The simulation domain extent in the  $z$ -direction is only one cell thick with periodic boundary conditions. Each spatial cell is a cube of length 228 km along each edge. Our velocity domain employs a sparse representation (von Althaus et al., 2014) and has a resolution of 30 km/s. The simulation domain is initialized with a somewhat fast and hot solar wind inflow of  $n_{p,sw} = 3.3 \times 10^6$  m $^{-3}$ ,  
100  $T = 0.5$  MK,  $\mathbf{V} = (-600, 0, 0)$  km/s, and either  $\mathbf{B}(S1) = (-5 \cos 5^\circ, 5 \sin 5^\circ, 0)$  nT or  $\mathbf{B}(S2) = 2\mathbf{B}(S1)$ . The Earth’s magnetic dipole is implemented at a realistic value of  $8.0 \times 10^{22}$  Am $^2$ , and the simulation domain inner boundary is a perfectly conducting sphere located at  $r = 31800$  km or about  $5 r_E$ . The simulation set-up results in solar wind Alfvénic Mach numbers of  $M_{A,1} \sim 10$  and  $M_{A,2} \sim 5$  and magnetosonic Mach numbers of  $M_{ms,1} \sim 5.4$  and  $M_{ms,2} \sim 3.8$  in front of the bow shock nose, and thus, strong fast-mode supercritical shocks. The simulations were run for  $t_{max,1} = 685$  s and  $t_{max,2} = 539$  s, respectively.  
105 To facilitate comparison with existing numerical studies, we note that for both simulation runs the solar wind ion inertial length is  $125.4$  km  $= 0.020 r_E$ , and for S1, the solar wind plasma beta  $\beta_1 = 2.3$ , and for S2,  $\beta_2 = 0.57$

Figure 1 depicts the Vlasiator simulation domain for simulation S1. The color map depicts proton densities, showing a dense magnetosheath between the bow shock and the magnetosphere, as well as variations in the upstream plasma density within the proton foreshock region. A thick fuchsia contour depicts where plasma density has increased two-fold over solar wind  
110 values, providing a rough estimate of the bow shock position. Thin black lines illustrate magnetic field lines, showing how the foreshock is permeated by fluctuations, as well as visualizing the complicated nature of magnetic flux compression and deflection at the quasi-parallel bow shock. The white circle indicates the simulation inner boundary, and two overlapping white rectangles indicate our regions of interest within the simulation. The larger white rectangle is used for visualizing test-particle studies of proton injection, whereas the smaller rectangle is used for analysis of quasi-parallel bow shock non-locality.

### 115 3 Vlasiator Results

In this section, we present results of hybrid-Vlasov simulations. First, we fit the global position of the bow shock using a quartic estimation and calculate the bow-normal angle to estimate the general direction of the shock normal. As our fit is so close to a parabola, we will henceforth for simplicity refer to it as a parabola. Then, we use several local measurements of

**Figure 1.** Overview of the Vlasior simulation S1 ( $B_{IMF} = 5 \text{ nT}$ ,  $M_A = 10$ ) at time  $t = 500 \text{ s}$ , with proton number density (colormap) overlaid with an estimate of the bow shock position according to plasma compression (thick fuchsia curve,  $n_p > 2n_{p,sw}$ ). Also shown are magnetic field lines (thin black curves) and two white overlapping rectangles indicating zoom-in regions used for analysis of local bow shock structure (smaller rectangle) and test-particle studies (larger rectangle).

plasma properties to estimate the rapidly moving and varying local position of the shock, and use their disagreement to define  
120 a non-locality of the shock.

### 3.1 Bow shock location and the shock-normal angle

In previous hybrid-method investigations into ion injection at kinetic plasma shocks, the shock descriptions have been usually  
either 1-D (see, e.g., Lyu and Kan, 1990; Scholer, 1990; Scholer and Terasawa, 1990; Onsager et al., 1991; Su et al., 2012)  
or if 2-D or 3-D, limited to local geometries (Guo and Giacalone, 2013; Caprioli et al., 2015; Hao et al., 2016; Sundberg  
125 et al., 2016; Caprioli et al., 2017). In a local planar shock, it is feasible to simply define the shock-normal direction from  
simulation box parameters and evaluate 1-D cuts along this line for defining the shock shape. However, as seen in Figure 1,  
in a global 2-D simulation, the curved bow shock has a bow-normal direction dependent on the nose angle  $\phi = \arctan(y/x)$ ,  
which complicates evaluating the shock-normal direction (Thomas and Winske, 1990). Shock and injection investigations  
within global simulations have recently been published in, e.g., Savoini et al. (2010, 2013); Karimabadi et al. (2014); Savoini  
130 and Lembège (2015).

We now determine a rough estimate of the global bow shock shape. We do this by finding the contour where plasma density  
increases two-fold over the solar wind value ( $n_p > 2n_{p,sw}$ ). The value of  $2n_{p,sw}$  was chosen based on visual inspection. We  
then fit a 4th order polynomial

$$r_s(\phi) = a_0 + a_1\phi + a_2\phi^2 + a_3\phi^3 + a_4\phi^4 \quad (1)$$

135 using the nose angle and the radial distance  $r = \sqrt{y^2 + x^2}$  at each contour position. This fit is performed at times  $t_0 = 438s$   
and  $t_f = 538s$ . We found that intermediate time steps are described well by performing linear interpolation in time of the  
polynomial coefficients.

One of the most commonly used criteria for defining the dynamics and injection characteristics of a shock is the shock-  
normal angle  $\theta_{Bn}$ , i.e., the angle between the shock-normal direction and the upstream magnetic field. The upstream magnetic  
140 field direction in the quasi-parallel shock region varies greatly due to upstream fluctuations (Greenstadt and Mellott, 1985).  
Thus, even within the quasi-parallel regime, the shock may exhibit a wide variety of shock-normal angles.

As the shock front evolves, reforms, and fluctuates, the local shock-normal direction also evolves. The local instantaneous  
shock-normal direction can end up being perpendicular or even reversed to the mean bow shock direction, and is thus challeng-  
ing to evaluate in a meaningful manner. In this study, we define an alternative measure, the *bow-normal direction*  $\hat{\mathbf{n}}'$ , which is  
145 the normal direction for the parabolic fit to the mean shape of the global shape of the shock front. This is calculated as

$$\mathbf{n}' = \left( -\frac{dr(\phi)}{d\phi} \cos \phi + r(\phi) \sin \phi, \frac{dr(\phi)}{d\phi} \sin \phi + r(\phi) \cos \phi, 0 \right) \quad (2)$$

and accordingly  $\hat{\mathbf{n}}' = \mathbf{n}'/n'$ . We use this bow-normal direction both for defining the bow-normal plasma bulk velocity compo-  
nent, used for calculating the magnetosonic Mach number of the shock, and for defining a bow-normal angle  $\theta_{Bn'}$ , describing  
the angle between the local wave-distorted magnetic field and the bow-normal direction.

### 150 3.2 Shock non-locality

The locations of quasi-perpendicular and subcritical collisionless plasma shocks can, for the most part, be estimated well due to the upstream remaining undisturbed. However, at supercritical quasi-parallel shocks, the upstream is characterized by magnetic and density fluctuations and an abundance of suprathermal particles. This can make defining the exact position of the quasi-parallel shock challenging. This localization is further hindered by the fact that the position of the shock changes locally at timescales related to shock reformation. Additionally, the global position of the shock changes at larger timescales due to variation in solar wind driving conditions. This non-stationarity of the shock is observed as, e.g., spacecraft encountering the shock multiple times during what is expected to be a single crossing (see, e.g., Lucek et al., 2002; Sundberg et al., 2016; Gingell et al., 2017). In order to investigate the injection problem, we now attempt to define the local quasi-parallel shock position within a larger shock transition zone (Burgess, 1995) on reformation-related timescales. We also present a method for quantifying the difficulty of defining the shock position.

We evaluate the location of the shock as a transition between the upstream and downstream conditions using three plasma properties. The first is plasma compression, using the previously introduced criterion of  $n_p > 2n_{p,sw}$ . The second is heating of the solar wind core population,  $T_{core} > 4T_{sw}$ , similar to the method of Wilson III et al. (2014b, a), with the value  $4T_{sw}$  selected based on visual inspection. The vliasiator distribution function is split into core and suprathermal parts ( $n_{p,core}$  and  $n_{p,st}$ ) by evaluating whether the solar wind frame ( $u_{sw,x} = -600$  km/s) velocity of particles is above or below  $v_{core,max} = 690$  km/s. The third criterion is when the plasma magnetosonic Mach number, calculated using the local fast magnetosonic mode speed and the bow-normal plasma bulk velocity, falls below 1. We do not include any criteria based on the magnetic field direction or magnitude, as they were found to provide poor results at the quasi-parallel bow shock. We emphasize that the presented methods will potentially register shocklets and SLAMS as they take part in the reformation process.

In Figure 2 we present in panels (a) and (b) snapshots of plasma density from simulations S1 and S2, respectively, at time  $t = 500$  s, zoomed in on the nose of the quasi-parallel bow shock. We have plotted the plasma density with overlaid contours representing the bow shock positions according to criteria for plasma density (fuchsia), solar wind core heating (green), and magnetosonic Mach number (pale blue).

The three contours are highly variable and in agreement with the position of the quasi-parallel shock only on the order of 50% of the time. We have selected four positions for profile cuts, depicted by black dashed lines in panel (a), showcasing different kinds of shock crossings. These simulate what a spacecraft might observe, except that they are spatial instead of temporal profiles. Line profiles for the three plasma properties used to gauge the shock position are shown in panels (c), (d), (e), and (f). Graphed quantities are scaled so that a value of 1 is where the shock is estimated to be. The distance between the positions of bow shock parametrization closest and farthest from the Earth can be considered the disagreement between the three parametrizations, and is shown as shaded gray regions. This distance estimates the uncertainty of the shock position, or the extent of the shock transition region within which the three plasma properties estimate the shock to be. We define this distance as the shock *non-locality*. It is defined in units of Earth radii instead of, e.g., upstream gyroscsles in order to facilitate comparison of bow shock structure sizes between different IMF conditions.

The cut shown in panel (c), at  $Y = 3.8r_E$ , shows regions of low plasma density in what would appear to be the downstream, likely a result of a new shock front forming at  $X \approx 11r_E$ , with the old shock position closer to  $X \approx 10.5r_E$ . Panel (d), at  $Y = 2.8r_E$ , shows active reformation of the quasi-parallel bow shock, with the first and last estimated shock positions disagreeing by over  $1.0r_E$ , as a new front is forming at  $X \approx 11.7r_E$ . The cut in panel (e), at  $Y = 1.2r_E$ , is an example of a well-defined shock front where all criteria agree, and panel (f) shows an intermediate case where the three criteria disagree somewhat and the shock transition seems to extend radially over a distance of several hundred kilometers. An animation depicting time evolution of Figure 2 is available as Supplementary Video A.

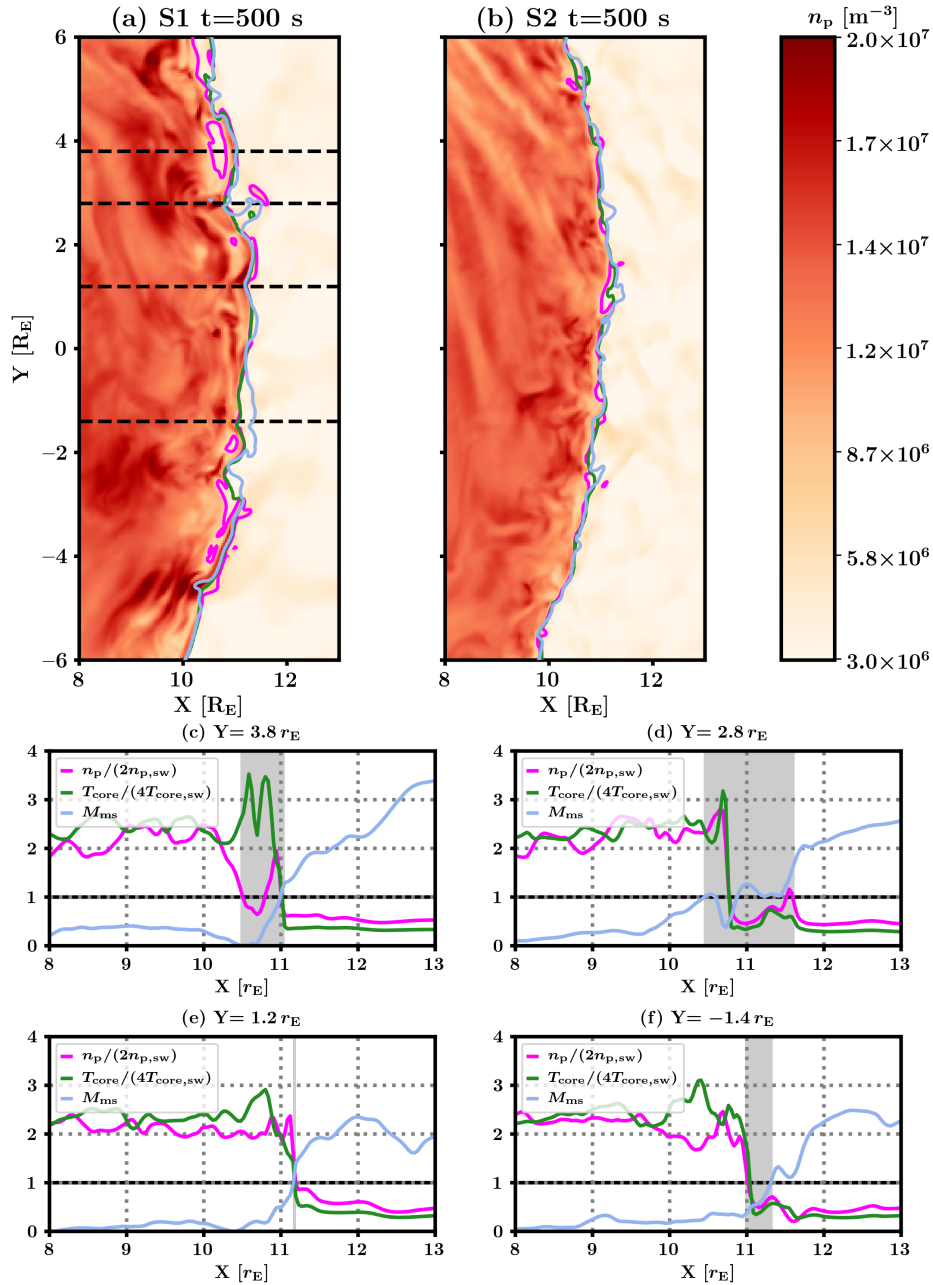

Quantifying the non-locality of the quasi-parallel bow shock using spacecraft data will be more challenging than for simulations. Simulations allow us to directly measure spatial scales, whereas spacecraft motion in relation to quasi-parallel reformation is slow, and thus, use of constellation spacecraft and multipoint techniques are usually needed in order to infer spatial scales. At Mercury this reformation has been studied through mainly magnetic field measurements in Sundberg et al. (2013).

We now describe how we evaluate the non-locality of the quasi-parallel bow shock in Vlasiator simulations. At one degree nose angle intervals, we draw a profile across the shock in the bow-normal direction, and measure where along the profile each of our three shock criteria (plasma density  $n_p = 2n_{p,sw}$ , solar wind core heating  $T_{core} = 4T_{sw}$ , and magnetosonic Mach number  $M_{ms} = 1$ ) indicate the local position of the shock is. Then, for each profile, we calculate the distance between the positions of bow shock parametrization closest and farthest from the Earth. This distance estimates the extent of the shock transition region, i.e., the non-locality of the shock. In Figure 3, panels (a) and (b), we plot stacked profiles displaying the temporal evolution of shock non-locality for simulations S1 and S2, respectively. Regions of enhanced shock non-locality appear to move along the shock front away from the nose region (indicated with a dashed line, as shown by the diagonal ridges. S1 shows significantly larger and clearer non-locality structures than S2. Still, there exists a qualitative similarity to the structures seen for both simulations. We note that the motion of structures away from the nose might be due to either deflected plasma flow carrying structures along the front, or due to foreshock wave fronts convecting in and interacting with a curved bow shock at increasing nose angle positions. In panels (c) and (d), we show logarithmic histograms of accumulated shock non-locality measurements, showing that a well-defined shock is the most common occurrence, and increasing non-locality is increasingly rare. This also confirms that S2 has, on average, lower measurements of shock non-locality than S1 does.

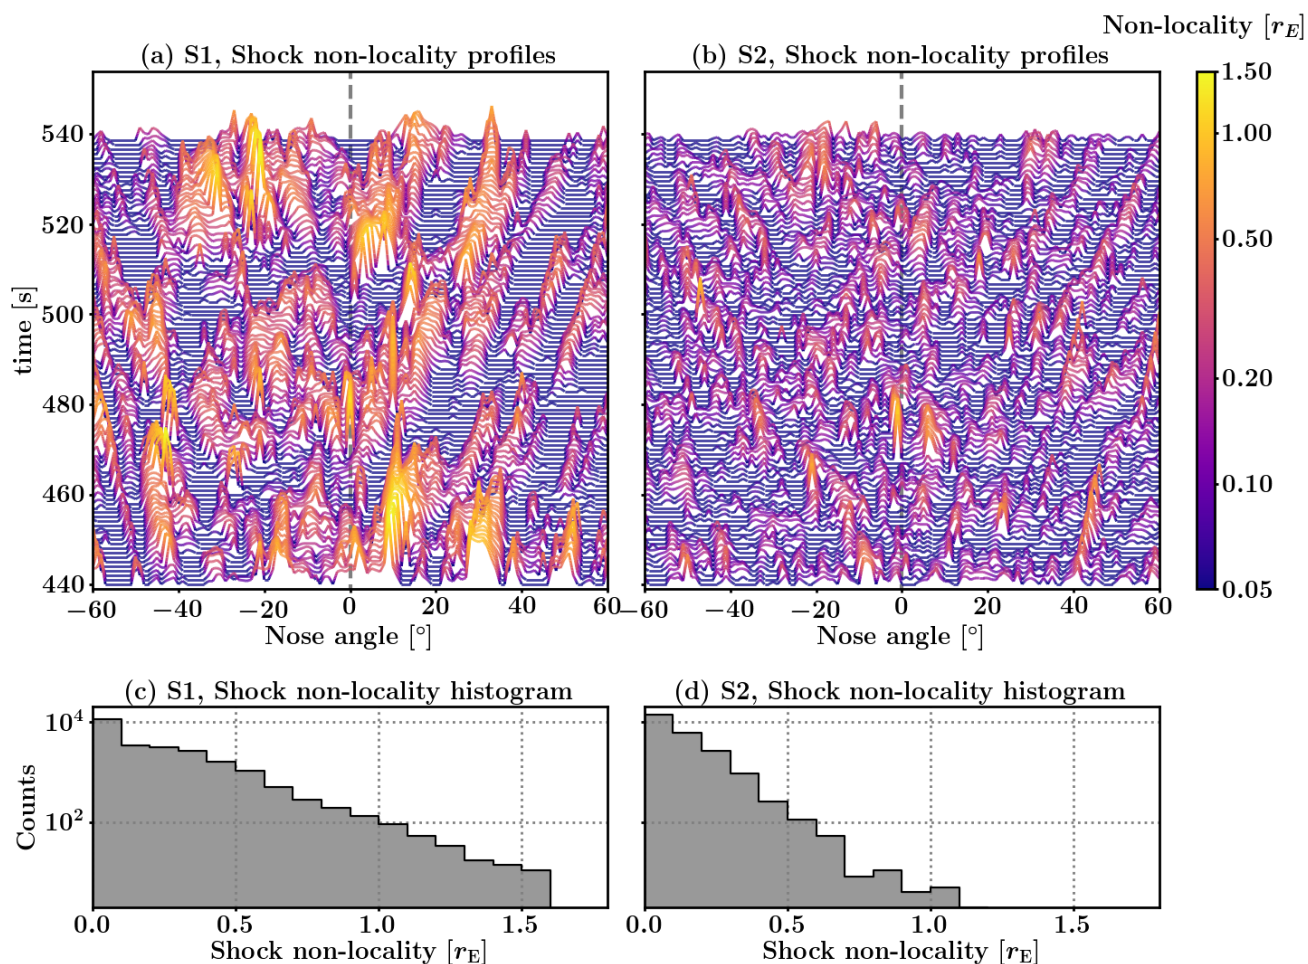

#### 4 Test-particle simulations

Following the evolution of distribution functions does not allow for tracing of particle histories. In order to evaluate injection probabilities, particles need to be tracked as they meet the bow shock and interact with it, ultimately either returning to the upstream or being transmitted to the downstream. Thus, we chose to use a test-particle method to track the motion of single protons within the electric and magnetic fields output from the Vlasiator simulation. The particle propagation uses a Boris-push algorithm (Boris, 1970) with a conservative time step of  $\Delta t = 0.005s$ . This time step is not limited by particle gyrotimes, but rather, ensures that particles up to  $10^5 eV$  travel less than  $1/10^{th}$  of a simulation cell per time step.  $\mathbf{E}$  and  $\mathbf{B}$  field values for each particle step are acquired from the Vlasiator output files using linear interpolation in both time and space.

**Figure 2.** Proton number density overlaid with bow shock positions according to criteria for plasma density (fuchsia,  $n_p = 2n_{p,sw}$ ), solar wind core heating (green,  $T_{core} = 4T_{sw}$ ), and magnetosonic Mach number (pale blue,  $M_{ms} = 1$ ). Panel (a) is for S1 ( $B_{sw} = 5$  nT), panel (b) for S2 ( $B_{sw} = 10$  nT), both at  $t = 500$  s. Panels (c–f) show line profiles of the three bow shock criteria along the dashed black lines shown in panel (a), corresponding with differing amounts of shock non-locality.

**Figure 3.** Profiles of measured shock non-locality as a function of nose angle. The  $y$ -axis lists simulation time, used as the base level corresponding with a well-defined shock with a non-locality measure of zero. Regions of enhanced non-locality are shown as colored peaks of the curve, as presented in the color bar. A dashed vertical line indicates nose angle  $0^\circ$ . (a): S1. (b): S2. Both plots show chains of enhanced non-locality regions, which move away from the nose region and decrease in intensity as they approach the flanks. Under each stacked profile plot we show a histogram depicting the occurrence rate of different non-locality levels, with panel (c) depicting S1 and panel (d) depicting S2.

Our goal is to use test-particle simulations to investigate proton injection at the quasi-parallel bow shock. For this purpose, we initialize our particles from the thermal solar wind core population, evenly distributed along a smooth curve a short distance in front of the bow shock. We follow the particles as they approach the shock region and interact with it. If a particle reaches again a boundary well in front of the shock, it is considered injected, and if it passes far into the downstream, it is considered transmitted. Once a particle has been flagged as injected or transmitted, it is no longer propagated. A significant portion of test-particles spend so much time within the shock structure that they are not flagged as either injected or transmitted at the end of the run, and their fate remains inconclusive.

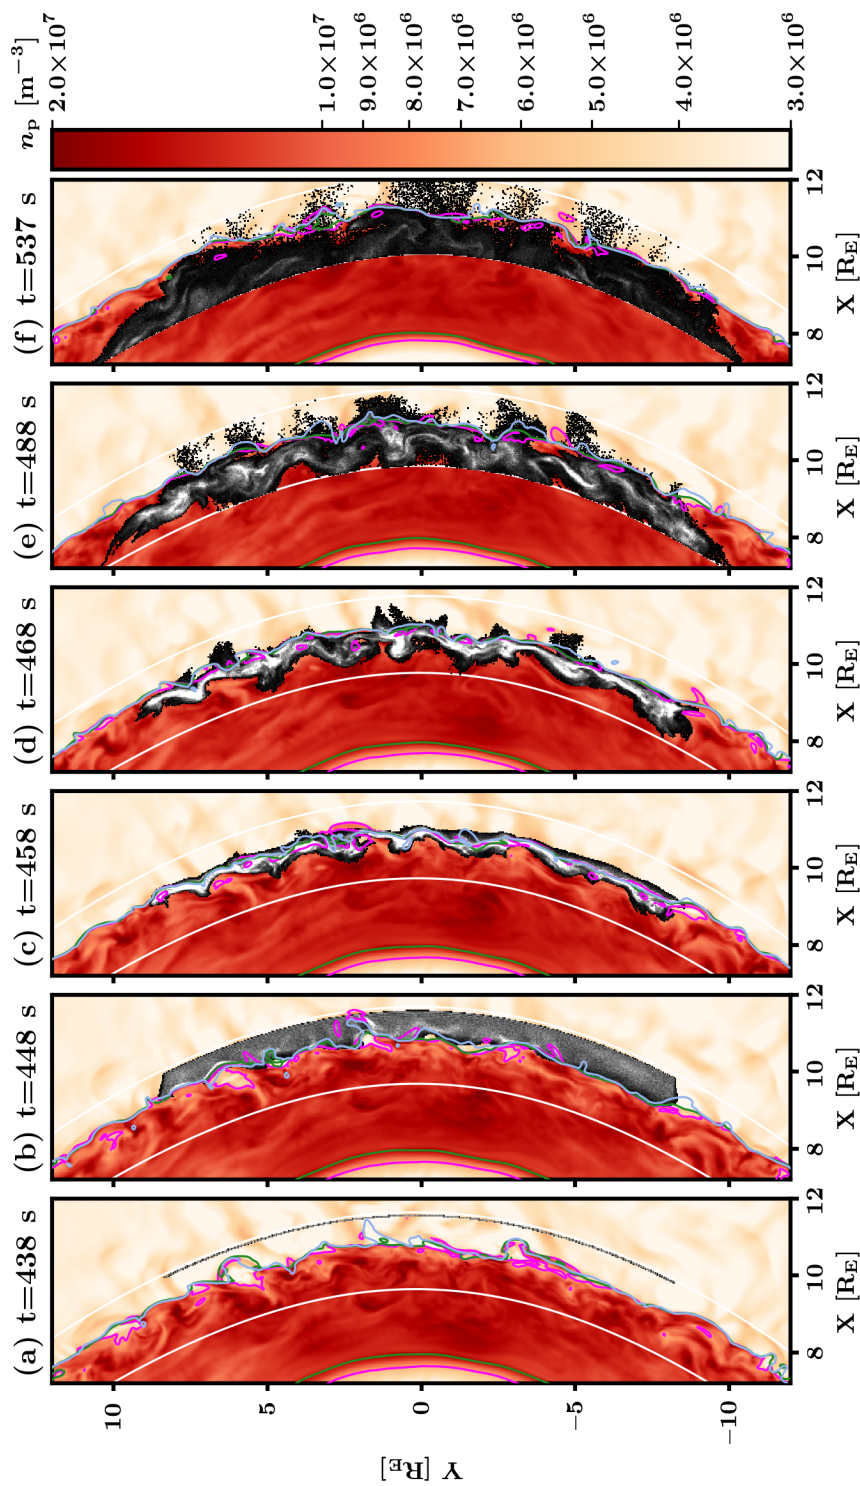

The particle initialization curve is placed  $0.9r_E$  outward of the parabolic bow shock fit, extending between nose angles  $\pm 40^\circ$ . This is visible in panel (a) of Figure 4 as the location of the first test-particles. An injection flagging boundary is placed  $0.1r_E$  beyond the injection curve, and a transmission flagging boundary is placed  $1.5r_E$  inward of the parabolic bow shock fit. These values were chosen so that the majority of changes to local quasi-parallel bow shock structure due to reformation fall within this region.

Each test-particle run consists of  $N = 10^5$  protons, initially isotropic in the frame co-moving with the inflow plasma, which results in a mean simulation frame energy of  $1.9\text{keV}$ . For each test run, particle velocities were chosen so they were monoenergetic (10, 20, 50, 100, 200, or 500 eV) in the inflow plasma frame and randomly distributed in direction. Additionally a Maxwellian test run was performed, with particles picked randomly from a Maxwellian 0.5 MK distribution centered in the inflow plasma frame. Particles were placed into the simulation as groups of 25000 particles every 0.5 s for 10 seconds, starting at  $t_0 = 438\text{s}$ . Particle propagation was halted at time  $t_f = 538\text{s}$ .

## 235 5 Test-particle results

In Figure 4, we display snapshots of test-particle propagation for simulation S1 and a plasma frame initialization energy of 100 eV. The grayscale region shows a logarithmic test-particle density, with black indicating single particles and white indicating over 100 particles per cell. We display contours parametrizing the shock position on top, and also plot two black parabolas which act as the injection and transmission flagging boundaries. Animations depicting the evolution of test-particle populations for all initialization parameters and simulations S1 and S2 are available in Supplementary Videos B and C, respectively.

The panels in Figure 4 show how solar wind protons start as an even curve (a), are launched into the simulation over 10 seconds, after which the first ones have already accumulated as white regions at the shock front (b). We note how the steepened structure at  $Y \approx 2r_E$  in panel (b) causes an accumulation of test-particles at its  $-Y$  edge, and that the regions of plasma depletion (fuchsia contour at, e.g.,  $Y \approx 6r_E$ ,  $Y \approx 2r_E$ , and  $Y \approx -3r_E$ ) remain void of test-particles at this time. By the time of panel (c), all test-particles have reached the shock transition region, the white regions of test-particle accumulation follow shock ripples, and many of the previously void regions have been filled with plasma. In panel (d) we see regions of efficient reflection causing particles to be returned to the upstream direction, but several regions also allow particles to move past the shock front and form into magnetosheath jets (Němeček et al., 1998; Hietala et al., 2009; Palmroth et al., 2018). By the time of panel (e), particles have spread to most of the magnetosheath all the way to the transmission boundary. Panel (f) displays how

**Figure 4.** Test-particle propagation for simulation S1, monoenergetic 100 eV initialization at 6 different times. Vlasiator simulation proton number density is overlaid with the logarithmic density of test-particles in greyscale, with white indicating over 100 particles in a cell. Two black parabolas are the transmission boundary (left) and the injection boundary (right). Three contours indicate estimates of the local shock position: plasma compression (fuchsia,  $n_p > 2n_{p,sw}$ ), solar wind core heating (green,  $T_{core} > 4T_{sw}$ ), and the magnetosonic Mach number (pale blue,  $M_{ms} < 1$ )

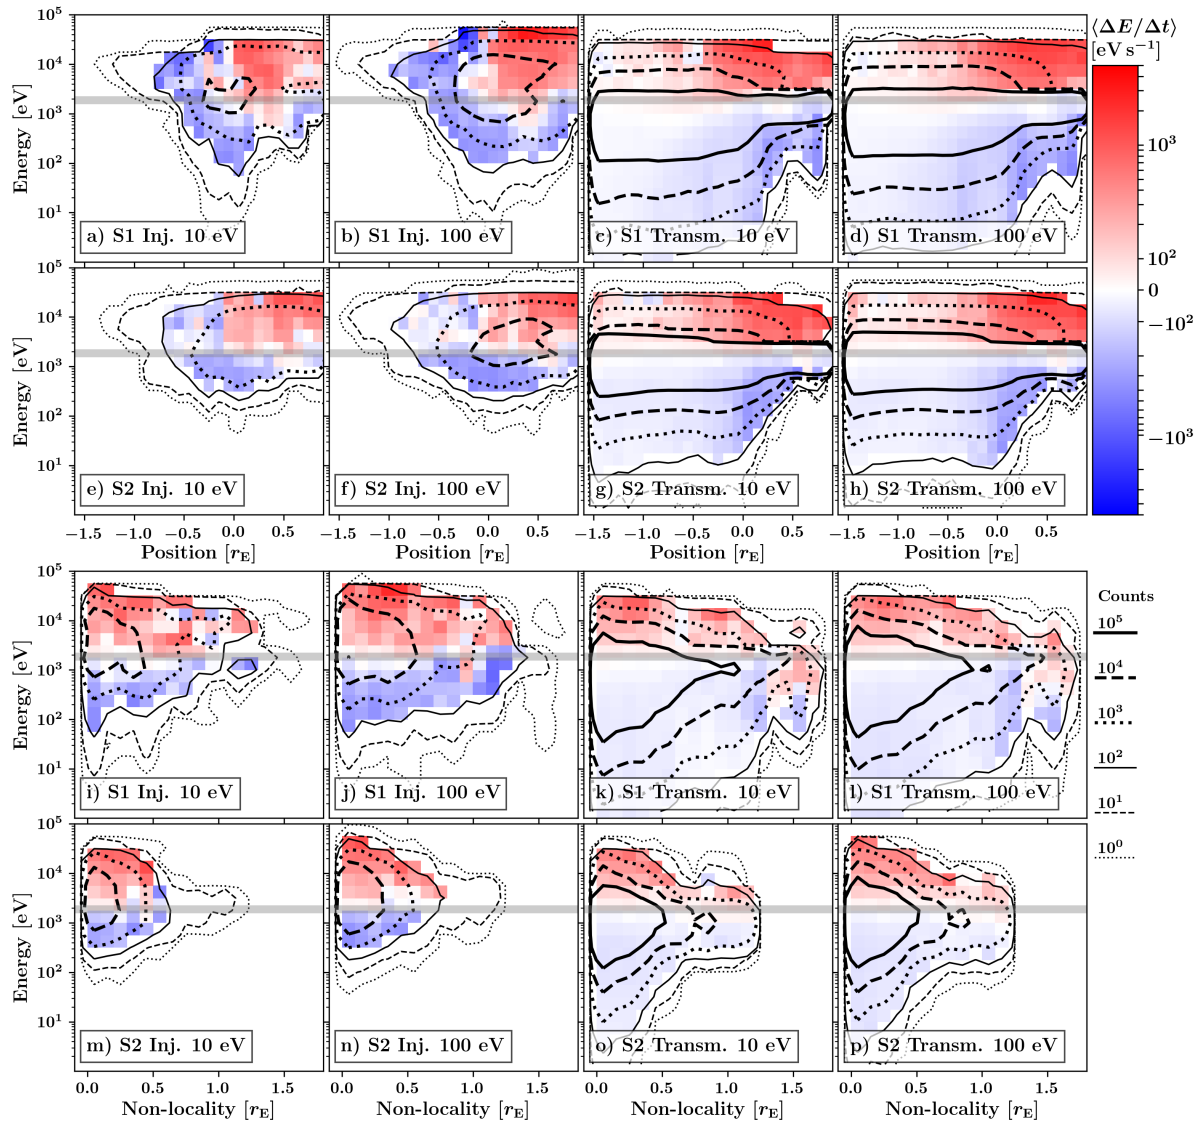

250 both transmission and injection can be slow processes, with 20–40% of particles still within the simulation after 90 – 100s of test-particle propagation, both in the upstream and in the downstream of the shock. For these particles, their ultimate fate of being injected or transmitted could not be evaluated from these simulations. Judging from panel (f) of Figure 4, a portion of these particles would likely be injected.

Evaluation of test-particle interactions with the shock structure as seen in Figure 4 did not provide a clear answer as to where  
255 within the shock transition region particles truly feel the impact of the shock. As a particle injected into the upstream necessarily will experience energization, we tracked the simulation frame energies of transmitted and injected particles and measured the regions where particles gained or lost the most energy. In Figure 5 we plot 2D-histograms of mean particle energy rate of change  $\langle \Delta E / \Delta t \rangle$ , which was calculated by gathering all particle energy changes over the whole test-particle simulation and normalizing the result with the amount of test-particles measured at each position in parameter space. The black contours  
260 depict logarithmic counts of measurements, starting from a single particle with the thin dotted line. The colormap of mean energization is only plotted where a minimum of 100 measurements were counted. We note that the energization colormap is a symmetric logarithmic plot, with a small linear region between  $\pm 100 \text{ eV s}^{-1}$ . The presented initialization energies of 10 and 100 eV correspond to  $44 \text{ km s}^{-1}$  and  $138 \text{ km s}^{-1}$  plasma frame velocities, respectively. We show energization plots for only those particles which were registered as transmitted or injected by the end of the test-particle simulation. A grey band indicates  
265 the mean energy of incoming solar wind particles in the simulation frame ( $1.9 \text{ keV}$  for  $600 \text{ km s}^{-1}$ ).

The single most clear result seen in Figure 5 is that in general, particles above the energy corresponding with the solar wind inflow speed ( $1.9 \text{ keV}$  for  $600 \text{ km s}^{-1}$ ) gain further energy, whereas particles with energies below that tend to lose energy. This is seen for both simulations S1 and S2. The first two rows, plotting energization as a function of simulation frame particle energy versus distance from the parabolic shock fit position  $r_s(\phi)$ , show that particles which end up injected can penetrate up  
270 to almost  $1.5 r_E$  into the downstream before returning upstream, but that those particles are a minority, and at high energies. These particles could perhaps be considered to be experiencing thermal leakage. The black contours depicting measurement counts show that particles dwell in the vicinity of the shock, and that area is also where injected particles have their lowest simulation frame energies. We also see that on average, injected particles gain energy throughout the upstream region, not only at the shock front itself. On average, injected particles decelerate in the downstream.

275 The behaviour of transmitted particles seen in Figure 5 is slightly different. They also reach lower simulation frame energies after passing the shock fit position, but they are found throughout the downstream region (by necessity, as they must reach the transmission boundary). Particles which end up transmitted appear to gain energy also in the downstream at energies  $E > 1.9 \text{ keV}$ , although the mean energization rate in that region is smaller. Similarly, the mean deceleration rate at energies  $E < 1.9 \text{ keV}$  is smaller in the downstream than in the upstream. Again, the region of efficient energization extends well upstream  
280 (up to  $1.0 r_E$ ) of the mean shock position.

The two bottom rows of Figure 5 evaluate mean energization of test-particles as a function of energy and shock non-locality. Particle count contours show that the majority of measurements are made at regions where the shock is well defined, i.e., the non-locality measure is low. However, comparing these counts with the statistics shown in Figure 3 shows that there is little to no preference for particles spending time in regions of high or low shock non-locality. Interestingly, it appears that the non-

**Figure 5.** Mean energization experienced by test-particles over their shock interaction. Energization tracking is performed separately for injected (columns 1 and 2) and transmitted (columns 3 and 4) particles. The top two rows track energization as a function of current particle simulation frame energy and position relative to the parabolic bow shock fit, and the bottom two rows as a function of current particle simulation frame energy and shock non-locality. Rows 1 and 3 are from Simulation S1, rows 2 and 4 are from S2. Black logarithmic contours indicate the counts of measurements used for evaluating mean energization, with values under 100 counts excluded. A grey band indicates the mean energy of incoming solar wind particles in the simulation frame ( $1.9 \text{ keV}$  for  $600 \text{ km s}^{-1}$ ). It is important to note that large values of shock non-locality can indicate signals of shock structure downstream as well as upstream of the parabolic shock fit position.

285 locality of the shock front does not affect mean energization rates either, as no clear preference for energization at low or high  
non-locality values can be seen. We do note that for simulation S1, at non-locality values of  $> 1.5r_E$ , we see energization also  
at lower energies, though this is mostly seen only for transmitted particles.

Finally, we calculate injection probabilities  $n_{inj}/(n_{inj} + n_{tra})$  for test-particles in runs S1 and S2 as functions of a selection  
of parameters (detailed below) describing the particle-shock-interaction. For each test-particle, we evaluate these properties at  
290 the first time the particle reaches a point in the simulation space that fulfills the solar wind core heating ( $T_{core} > 4T_{sw}$ ) criterion.  
Due to the non-locality of the quasi-parallel shock front, estimating when the particle-shock interaction is most significant is  
challenging, so we simply chose one of our shock criteria.

In Figure 6, we plot the estimated injection probabilities for test-particle runs using S1 and S2, using six different solar wind  
frame initialization energies and a Maxwellian initialization. The first two rows use properties of particles in the simulation  
295 frame, namely the pitch-cosine  $\mu = \cos(\alpha)$  (where  $\alpha$  is the angle between the particle velocity and the local magnetic field  
direction), and the incidence angle (the angle between the particle direction of travel and the opposite of the bow-normal  
direction  $\angle(\mathbf{v}, -\hat{\mathbf{n}})$ ).

The last three rows of Figure 6 use shock properties, namely the local bow-normal angle  $\theta_{Bn'}$ , the local shock position  
non-locality, and the impact position nose angle. Error bars are provided by the Agresti-Coull method with a 95% confidence  
300 interval.

The first row of Figure 6 indicates that if the particle encounters the shock with negative pitch-cosine, it is likely to be  
injected. In our simulation set-up, most particles travel roughly in the  $-v_x$  direction, and with the IMF pointing roughly anti-  
sunward, most particles have pitch-cosines close to 1. Significant deviation from this suggests local magnetic field directions  
which have changed significantly due to foreshock wave effects. Our results indicate that these magnetic field deflections can  
305 enhance injection probabilities.

According to the second row, if the particle has a large incidence angle (the bow-normal velocity component is positive or  
small compared to the bow-perpendicular velocity component), injection is again likely. Incidence angles above  $90^\circ$  in fact  
suggest the particle was travelling away from the bow shock when it first met a shock structure. This could perhaps happen due  
to the particle gyrating along a deflected magnetic field line with a pitch-angle close to zero, so that its perpendicular velocity  
310 causes it to encounter a shock peninsula such as the one seen at  $Y = 2.8r_E$  in Figure 2 from behind. We note that these plots  
show on average larger injection probabilities for higher plasma frame particle initialisation energies. This is as expected,  
as higher plasma frame initialization energies enable greater maximum energies when transforming into the spacecraft or  
simulation frame.

The third row shows injection probability as a function of the local bow-normal angle  $\theta_{Bn'}$ . For S1, we see a small bump  
315 for low initialization energies at  $\sim 70^\circ$ , and a significant increase at all energies at  $\sim 85^\circ$ . Considering bow-normal angles  
above  $90^\circ$  may seem odd, but these regions are where foreshock fluctuations and shock effects have caused the local magnetic  
field to twist back on itself. For simulation S2, with a lower Mach number, these situations are not registered. The fourth row  
indicates injection probability as a function of the shock non-locality measure. Both simulations S1 and S2 show a peak in  
injection probability at a non-locality value of  $0.4r_E$ , with even the lowest initialisation energies having a  $\sim 10\%$  probability

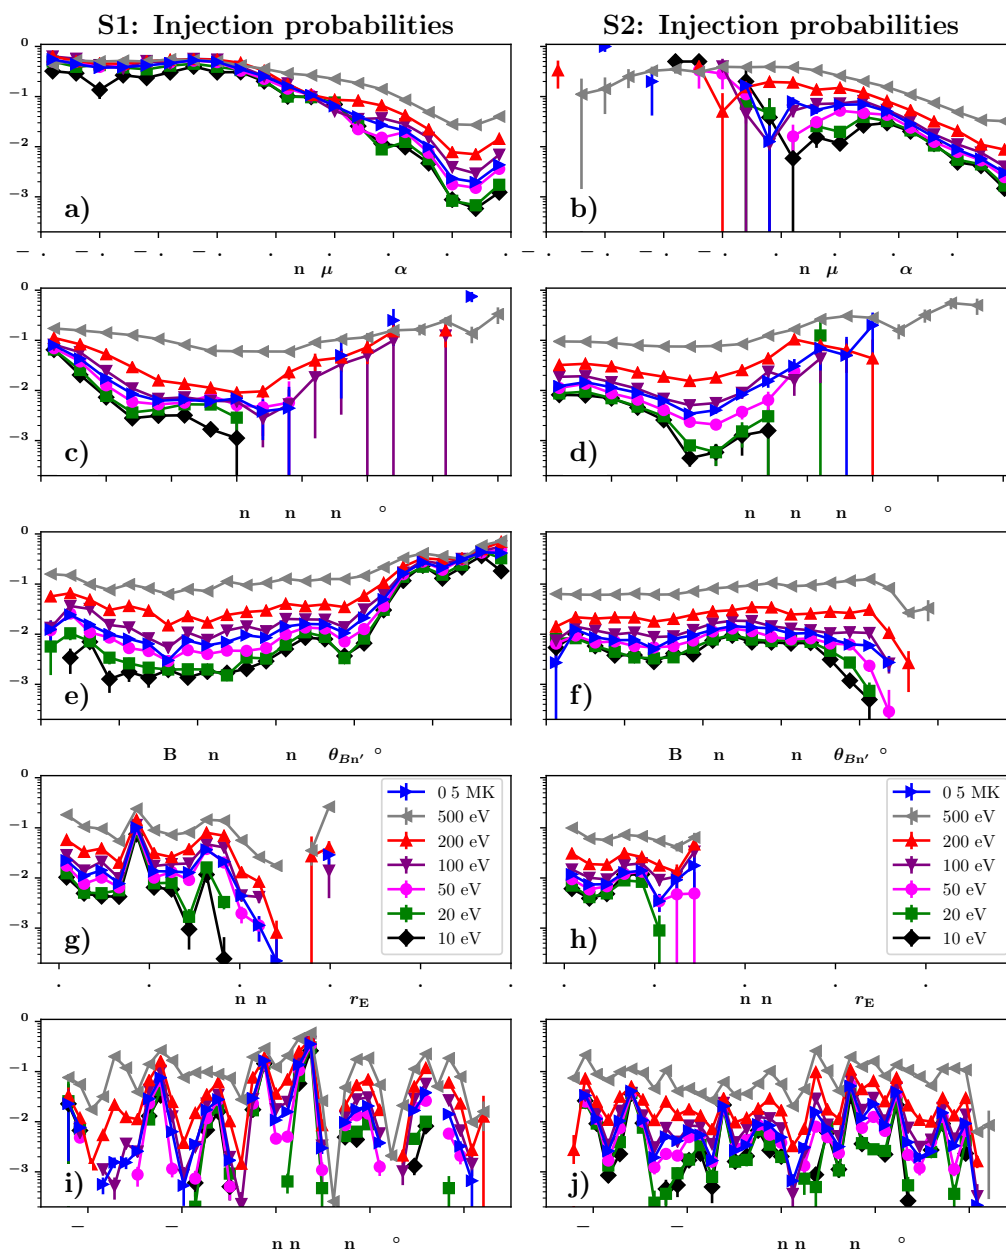

320 in S1. For simulation S1, there is a decline in injection probability as the non-locality value increases beyond  $\sim 0.8 r_E$ , with  
an additional peak of injection at energies  $> 100$  eV at  $1.5 r_E$ . Simulation S2 did not exhibit large values on non-locality so  
the peak at  $1.5 r_E$  cannot be verified, but there is a decrease in injection probability for 10 and 20 eV initialization energies  
when going to non-locality values of  $\geq 0.5 r_E$ . The fifth row, showing injection probability as a function of global position  
(nose angle) indicates that despite particles being energized over large radial distances, and there being no strong indication of  
325 shock non-locality affecting injection, there are regions along the shock front where local deformed shock and magnetic field  
structures enhance particle injection significantly. We attempted to smooth out some of these effects by launching test-particles  
into the simulation over a duration of 10 seconds, but an even longer test-particle initialisation and simulation extent would  
likely be required to smooth out all of these effects. In this study, we were limited by the fact that simulation S2 ended at time  
 $t_f = 537$  s.

330 As a final step, in Table 1 we display the overall calculated injection probabilities  $N_{inj}/(N_{inj} + N_{tra})$  per test-particle run for  
six test-particle initialization energies and a Maxwellian initialization. Due to the limited time period of test-particle propaga-  
tion, at the end of the run a portion of particles were still within the shock transition zone. This is indicated by the completion  
ratio  $(N_{inj} + N_{tra})/N_{init}$ . We find that the completion rate for S1 rises somewhat with increasing initialization energy, but is very  
stable for S2. In agreement with expectations, the injection rate increases monotonically with greater initialization energies.  
335 The injection rates for Maxwellian distributions are located between the values for 50 eV and 100 eV initializations, where the  
thermal speed for the 0.5 MK Maxwellian distribution is approximately 100 eV. As a point of comparison, we also extracted the  
Vlasiator simulation suprathermal particle densities at positions  $0.5 r_E$  and  $1.0 r_E$  upstream of the shock, averaged over nose  
angles  $\pm 45^\circ$  and between simulation times  $t_0 = 438$  s and  $t_f = 538$  s. To facilitate comparison of these Vlasiator suprathermal  
particle densities  $\langle n_{p,st} \rangle$  with test-particle injection probabilities, the values are given in units of solar wind density and in-  
340 cluded as the final two rows of Table 1. The order of Vlasiator S1 and S2 upstream suprathermal particle densities as a function  
of Mach number is thus opposite to that of test-particle injection probabilities. This effect may be caused by the differing scales  
of foreshock structures, with S2 foreshock dynamics causing clumped enhancements of reflected particles in the vicinity of the  
shock, and the strong ULF and SLAMS signatures in S1 causing corresponding rarefactions as well as enhancements. This  
phenomenon was investigated in Turc et al. (2018), as shown in their Figure 2, panels b through d.

## 345 6 Discussion

We now discuss our results presented in sections 3 and 5, attempting to clarify questions related to the non-locality of the  
quasi-parallel bow shock and thermal particle injection at the Earth's quasi-parallel bow shock. We note that our approach  
has a number of differences compared with previous shock injection studies. We make no pre-selection that particles must  
encounter the shock with only a single big energization like, e.g., Sundberg et al. (2016) do. We track particle injection based  
350 on a spatial boundary, instead of requiring the ion to achieve a given energy. In our simulation the mean solar wind energy  
or the shock ram energy is  $E_{ram} = \frac{m_i}{2} (M_A v_A)^2 \approx 1.9$  keV, and a requirement of 5–10 times this energy for particle injection  
(such as required by Caprioli et al., 2015) is met by approximately 40%-50% of our injected particles. We additionally note

**Figure 6.** Test-particle injection probabilities for six different solar wind frame initialization energies and a 0.5 MK Maxwellian initialization and five different parameters. Left column: S1. Right column: S2. Rows 1 and 2 show properties of particles, namely the pitch-cosine  $\mu = \cos(\alpha)$  and the incidence angle. Rows 3 through 5 show shock properties, namely the local bow-normal angle  $\theta_{Bn'}$ , the local shock porosity, and the impact position nose angle. Error bars are provided by the Agresti-Coull method with a 95% confidence interval.

**Table 1.** Test-particle proton statistics using simulations S1 ( $M_A \approx 10$ ) and S2 ( $M_A \approx 5$ ) with six different solar wind frame initialization energies  $E_{\text{init}}$  and also a Maxwellian initialization distribution with a temperature of 0.5 MK. Columns list the estimated injection probability  $N_{\text{inj}}/(N_{\text{inj}} + N_{\text{tra}})$  and the completion ratio  $(N_{\text{inj}} + N_{\text{tra}})/N_{\text{init}}$ . Also shown is the ratio of injection probabilities for S2 and S1. The final two rows show suprathermal proton density measurements  $\langle n_{p,\text{st}} \rangle$  extracted from Vlasiator simulations S1 and S2, at positions  $0.5 r_E$  and  $1.0 r_E$  upstream of the mean bow shock position, averaged over nose angles  $\pm 45^\circ$  and the test-particle run time extent.

Test-particle $E_{\text{init}}$	S1 injection	S1 completion	S2 injection	S2 completion	S2/S1 injection ratio
10 eV	0.011	0.58	0.0058	0.79	0.53
20 eV	0.013	0.59	0.0063	0.79	0.48
50 eV	0.018	0.59	0.0086	0.79	0.48
100 eV	0.027	0.60	0.013	0.78	0.48
200 eV	0.047	0.62	0.027	0.77	0.75
500 eV	0.13	0.67	0.085	0.77	0.65
Maxwellian	0.021	0.59	0.010	0.78	0.48
Vlasiator suprathermals	$\frac{\langle n_{p,\text{st}}(S1) \rangle}{n_{p,\text{sw}}}$		$\frac{\langle n_{p,\text{st}}(S2) \rangle}{n_{p,\text{sw}}}$		$\frac{\langle n_{p,\text{st}}(S2) \rangle}{\langle n_{p,\text{st}}(S1) \rangle}$
at $r_{\text{shock}} + 0.5 r_E$	0.042		0.061		1.45
at $r_{\text{shock}} + 1.0 r_E$	0.027		0.037		1.37

that the complicated global shock geometry used in our study prevents use of simple injection measures such as a positive  $v_x$  component (Sundberg et al., 2016). We note that in modeling the cross-shock potential we neglect the electron pressure gradient term. The majority of the potential difference at the shock is, however, included in the Lorentz and Hall terms (Eastwood et al., 2007; Yang et al., 2009).

Examination of Figure 2 shows that the spatial structure of bow shock non-locality depends on the magnitude of the upstream magnetic field, and thus, the spatial scale of foreshock structures. In Figure 3, it is evident that S1 shows clearer structures and stronger peaks of non-locality. The fine structure seen in S2 is as expected due to the increased magnetic field strength, which gives rise to smaller-scale structures in the foreshock and higher frequencies for the ULF waves (Turc et al., 2018), which in turn are expected to drive shock reformation.

We also investigated the energization taking place during the first shock encounter of particles, before acceleration per se. We found that all examined particles had their efficient increases and losses of energy taking place in the larger shock transition region and extending up to  $1 r_E$  into the upstream, not limited to a narrow shock front position. Particles did, however, dwell for longer at the mean shock front position (panels a, b, and f of Figure 5). We found that the majority of reflected particles did not penetrate far into the downstream, but a few did, and as they had achieved high energies, they might constitute injection through thermal leakage from the downstream. As we initialized our particles isotropic in the upstream plasma frame, we could see that particles which had simulation frame energies below the mean solar wind energy were preferentially decelerated, and particles above this energy were preferentially energized. This is opposite to what Johlander et al. (2016) reported, as they saw

370 slow particles reflected at SLAMS, with fast particles passing through them. This suggest that the ubiquitous energization we see is not associated with only SLAMS, but also other foreshock processes. A new finding which may be related is that of localized reconnection found in the quasi-parallel shock transition region (Gingell et al., 2019).

Interestingly, our result of energization taking place over a large area contradicts the results of, e.g., Guo and Giacalone (2013), who in simulations of a  $M_A = 4$  shock saw initial energization very close to the shock (within  $\sim 10 c/\omega_{ci}$  of the shock, 375 or in our nomenclature,  $\sim 0.2 r_E$ ). The size of bow shock reformation in our simulation is (at  $\sim 50 c/\omega_{pi}$ ) in agreement with the results of, e.g., Omidi et al. (2013) and Caprioli and Spitkovsky (2013).

We also evaluated particle energization as a function of shock non-locality, and found little dependence. For the most part, energization rates appear to be equal at all non-locality values, although a weak signature of energization of slower particles could be seen if the associated shock non-locality value reached  $\sim 1.5 r_E$ . This might be associated with bow shock bulges or 380 erosion, as reported in Blanco-Cano et al. (2018).

Statistical analysis of correlations between shock and particle properties and injection probability is presented in Figure 6. The most obvious result is that there are very few particles at large incidence angles, especially at lower initialization energies. For S1, there appears to be a connection between enhanced injection probability and incidence angles close to zero. A small incidence angle will likely correlate with greater-than-average inertial frame initialization energy, and higher energy is known 385 to increase injection probability.

The third row of Figure 6 highlights the importance of magnetic field deflections upstream and at the shock for efficient particle injection. Simulation S1 is much more efficient at forming strong deflections, resulting in bow-normal angles of above  $80^\circ$ , whereas they are absent in S2. We emphasize that these measurements were performed within the globally quasi-parallel region of the bow shock, between nose angles  $\sim \pm 40^\circ$ . We also note that in S1, there is an increase in injection at low 390 initialization energies for bow-normal angles  $\leq 15^\circ$ . This is likely the same effect as what Sundberg et al. (2016) described as injected ions encountering a locally quasi-perpendicular field downstream of the shock. This also warrants further investigation.

The fourth row of Figure 6 evaluates the link between shock front non-locality and proton injection. Both simulations S1 and S2 exhibit a peculiar peak in injection probability at  $\sim 0.4 r_E$ , with the peak especially strong in S1. S2 does not exhibit large non-locality values, but for S1, injection probability seems to fall past values  $\sim 0.9 r_E$ , with another peak at  $\sim 1.5 r_E$ . At 395 low initialization energies, injection probabilities appear to fall off faster with increasing non-locality of the shock.

The final row of Figure 6 shows that on time scales represented in our test-particle simulations, local structures of the quasi-parallel bow shock do have a significant effect on particle injection at all initialization energies. This is likely akin to what, e.g., Hao et al. (2017) and Sundberg et al. (2016) reported on, with rippled shapes of the shock front and advected magnetic fluctuations resulting in regions of localized injection. The non-locality of the quasi-parallel bow shock and its influence on 400 the injection problem will thus need additional study and more comprehensive analysis of local shock and magnetic field structures.

The overall injection probabilities inferred from our test-particle studies agree with the strength of the shock (and the Alfvénic Mach number) indicating the overall injection probability of the shock. However, we note that the suprathermal particle density registered in the upstream of the shock did not agree with this result, indicating that the evolution of suprather-

405 mal particle populations throughout the foreshock is a complicated process and not a simple indicator of local shock reflectivity. One important effect to note is that of particle trapping between foreshock waves, as reported by Wu et al. (2015). We suggest that when performing studies of shock reflectivity using spacecraft measurements, extra care should be taken to differentiate freshly injected particles from an evolved foreshock population.

## 7 Conclusions

410 We have investigated the dynamics of the reforming quasi-parallel bow shock of the Earth in connection with the injection of thermal solar wind protons, using both hybrid-Vlasov and test-particle studies. Our high-fidelity hybrid-Vlasov simulations have allowed us to probe the reforming quasi-parallel bow shock dynamics in greater detail than previously possible, accounting for the global dynamics of bow shock curvature and for effects stemming from tenuous upstream particle distributions. Our results have shown that the energization and injection of solar wind ions within this region are not local effects taking place  
415 at a single shock location, but rather, are spread out over a larger shock transition region spanning at least  $1.0 r_E$ . We confirm enhanced particle injection with higher Alfvénic shock Mach number, and plasma frame particle energy, as expected. We also find that whenever the shock-associated magnetic field is deflected a great deal, particle injection is enhanced. A weak enhancement could also be seen in one of our simulations at very small bow-normal angles  $\theta_{Bn'}$ , so the interaction of magnetic field directions just upstream and downstream of the shock requires further study.

420 In our investigation, we defined a new metric for the bow shock, indicating the magnitude of non-locality of the shock front, associated with reformation. This metric was seen to correlate with the parameters of the foreshock and associated fluctuations, and also thus the shock Alfvénic Mach number. We found little to no correlation between solar wind ion injection probability and the shock non-locality, which is in agreement of our finding of particle energization within the quasi-parallel bow shock region taking place over a large upstream extent, not only at the local or non-local shock front.

425 Our study concentrated on two bow shock simulations, so additional studies into the locality of injection and energization of solar wind particles is warranted, using a more extensive simulation database.

We further note that the local density of suprathermal particles may be a poor indicator of injection efficiency of the shock due to large-scale dynamics of the foreshock region, such as particle trapping. This is an important factor when using either simulation results or spacecraft observations for estimating injection efficiencies at the bow shock.

430 *Code and data availability.* Vlasiator (<http://www.physics.helsinki.fi/vlasiator/>, Palmroth, 2018) is distributed under the GPL-2 open source license at <https://github.com/fmihpc/vlasiator/> (Palmroth and the Vlasiator team, 2018). Vlasiator uses a data structure developed in-house (<https://github.com/fmihpc/vlsv/>, Sandroos, 2018), which is compatible with the VisIt visualization software (Childs et al., 2012) using a plugin available at the VLSV repository. The Analysator software (<https://github.com/fmihpc/analysator/>, Hannuksela and the Vlasiator team, 2018) was used to produce the presented figures. The run described here takes several terabytes of disk space and is kept in storage  
435 maintained within the CSC – IT Center for Science. Data presented in this paper can be accessed by following the data policy on the Vlasiator web site.

*Video supplement.* The Supplementary Videos A, B, and C provide movie extensions of Figures 2 and 4, showcasing the evolution of the quasi-parallel shock front profiles and the associated non-locality (Video A) and the evolution, transmission, and injection of test-particle populations of various initialization parameters for simulations S1 (Video B) and S2 (Video C).

440 Movie A. Movie extension of Figure 2. Animation of proton number density overlaid with bow shock positions according to criteria for plasma density (fuchsia,  $n_p = 2n_{p,sw}$ ), solar wind core heating (green,  $T_{core} = 4T_{sw}$ ), and magnetosonic Mach number (pale blue,  $M_{ms} = 1$ ). Panel (a) is for S1 ( $B_{sw} = 5$  nT), panel (b) for S2 ( $B_{sw} = 10$  nT), both at  $t = 500$  s. Panels (c–f) show line profiles of the three bow shock criteria along the dashed black lines shown in panel (a), corresponding with differing amounts of shock non-locality.

445 Movie B. Movie extension of Figure 4. Test-particle propagation for simulation S1 ( $B_{sw} = 5$  nT), with 6 different monoenergetic initialization as well as a Maxwellian 0.5 MK initialization. Vlasiator simulation proton number density is overlaid with the logarithmic density of test-particles in greyscale, with white indicating over 100 particles in a cell. Two black parabolas are the transmission boundary (left) and the injection boundary (right). Three contours indicate estimates of the local shock position: plasma compression (fuchsia,  $n_p > 2n_{p,sw}$ ), solar wind core heating (green,  $T_{core} > 4T_{sw}$ ), and the magnetosonic Mach number (pale blue,  $M_{ms} < 1$ ).

450 Movie C. Movie extension of Figure 4. Test-particle propagation for simulation S2 ( $B_{sw} = 10$  nT), with 6 different monoenergetic initialization as well as a Maxwellian 0.5 MK initialization. Vlasiator simulation proton number density is overlaid with the logarithmic density of test-particles in greyscale, with white indicating over 100 particles in a cell. Two black parabolas are the transmission boundary (left) and the injection boundary (right). Three contours indicate estimates of the local shock position: plasma compression (fuchsia,  $n_p > 2n_{p,sw}$ ), solar wind core heating (green,  $T_{core} > 4T_{sw}$ ), and the magnetosonic Mach number (pale blue,  $M_{ms} < 1$ ).

455 *Author contributions.* MB carried out the analysis and wrote the manuscript. UG and YPK have made significant contributions to the simulation methods and analysis. All co-authors helped in the interpretation and visualization of the results, read the manuscript, and commented on it.

*Competing interests.* The authors declare that they have no conflict of interest.

460 *Acknowledgements.* We acknowledge the European Research Council for Starting grant 200141-QuESpace, with which Vlasiator (Palmroth, 2018) was developed, and Consolidator grant 682068-PRESTISSIMO awarded to further develop Vlasiator and use it for scientific investigations. The Finnish Centre of Excellence in Research of Sustainable Space, funded through the Academy of Finland grant number 312351, supports Vlasiator development and science as well.
