Anonymous Referee #2: Interactive comment on “A case study of the day-to-day occurrence of plasma irregularities in low-latitude ionosphere from multi-satellite observations” by Weihua Luo et al. Received and published: 18 November 2019

The paper studied the occurrence of ionospheric plasma irregularities (bubbles and blobs) on days 17 and 18 of August 2003 over the longitude of 170° using data of the ROCSAT-1, DMSF, Grace and CHAMP satellites. They successfully detected these irregularities as signatures on the ion density measured by these satellites and they also used the ratio $[O/N_2]$ from GUVI to support the presence of vertical neutral wind.

C1

Even though the authors presented many discussions about the physical mechanisms responsible for the irregularities they need to consider the following points/suggestions:

Response: We would like to thank the reviewer for her/his invaluable comments and suggestions on our study.

- the authors presented many well-known (for decades) physical mechanisms and conclusions;- the paper doesn't present any new insight and data do not support the suggestions for these mechanisms;

Response: In this manuscript, we report the occurrence of the plasma bubbles and blobs in two successive days under quiet and disturbed conditions, respectively. The variations of Equatorial Ionization Anomaly (EIA) during the two days were similar. The interesting results can be summarized as, 1) The EIAs were strengthened during the quiet day (17 August) and the disturbed day (18 August), which means the zonal electric fields were enhanced. On the disturbed day, the enhancement of electric field can be attributed to the Prompt Penetration Electric Field (PPEF). On the quiet day, we prove that the enhancement was not associated with the PPEF, which may be related with the lower atmosphere, such as Large-Scale Wave Structure (LSWS). 2) The EIAs became asymmetric in these two days, which may be associated with the meridional wind. Generally, the plasma bubble is preferable to occur when the EIA is symmetric because of the absent of the meridional wind. When the co-existence of enhanced eastward electric field and meridional wind, the competition of the two factors should be considered. On 17 and 18 August, the eastward electric fields were enhanced and lead to the occurrence of irregularities, though the EIA became asymmetric due to the existence of meridional wind. Furthermore, the enhanced eastward electric field will strengthen the EIA, and the occurrence of vertical wind in equatorial region, which are preferable to the generation of plasma bubbles. From the results, we can speculate that the effects of enhancement of eastward electric field play the first important role in the occurrence of irregularities, while meridional wind may play the secondary important role in the occurrence of irregularities. The factors leading to the enhancement of

C2

eastward electric field under quiet condition need to be further investigated, which may be the key factor for the day-to-day occurrence of plasma irregularities in equatorial and low-latitude ionosphere.

- the authors observed (line 157) westward bubble movements for the quiet (17th) and for the disturbed day (18th). Normally the bubbles drift to east during magnetically quiet days and this movements reverts to west during disturbed days. How the authors explain this?

Response: As the reviewer pointed out, the bubbles usually move to east during magnetically quiet days and reverts to west during disturbed days. It's our carelessness that the movements of the bubbles were not discussed in the manuscript. In Figure 1 and Figure 2, the plasma inside the irregularities moved westward and the ambient plasma moved eastward. The drifts satellite detected were the plasma drifts, not the bubble drifts. As Huang et al. (2010) reported, the zonal drift velocity of the plasma particles inside plasma bubbles is significantly different from the ambient plasma drift. The relative zonal velocity of the ions inside the depletion region with respect to the ambient plasma is generally westward. The drifts shown in Figure 1 and Figure 2 are normal and reasonable.

- the authors observed plasma irregularities on both quiet (17 th) and disturbed day (18 th). For the quiet day they suggest that waves (LSWS, PW, GW) propagating upward (from down) contributed to trigger the irregularities while during the disturbed day they attributed the PPEF as the main cause for the irregularities generation. They pointed out that there were no irregularities on the other days of August 2003 (non-irregularity

C3

season at that longitudinal sector). Why these upward waves were so active on day 17 and not at the other days of August? No support for these upward waves is presented.

Response: On 17 August, a quiet day, the EIA was strengthened and became asymmetric, which means the existence of enhanced eastward electric field and meridional wind. The background zonal electric field was not affected by the factors from the upper, e.g. penetration electric field. The factors from the lower atmosphere may also enhance the F-region electric field. Thus, we speculate that the background zonal electric field was strengthened due to the Large-Scale Wave Structure (LSWS), which may be a key factor to the day-to-day occurrence of irregularities in equatorial and low-latitude ionosphere. In fact, we also do not know why the waves were so active on 17 August. We want to study the effects of the LSWS on the zonal electric field in F-region. Unfortunately, we cannot access any observational data or model simulation to prove this speculation.

- at Figure 4, using DMSP data at 840 km large ion density is observed on day 18 at geomagnetic equator while large ion densities are observed at the EIA crests (see Figure 5 , CHAMP and Grace data) with no ionization at magnetic equator. Even though the altitudes of DMSP and CHAMP/GRACE satellites are different it is expected that high density peaks at the EIA crests comes from magnetic equator. How authors explain this? Here also another comment: there are differences between geomagnetic equator (Figure 4) and magnetic equator (Figure 5). The authors should standardize this or was it a typo error?

Response: On 18 August, the ion densities at the equator and EIA crests were large at 400 km and 840 km. Due to the "fountain effect", the plasma at the higher altitude and lower latitude (equatorial region) would diffuse along the field line to the lower altitude and higher latitude. At DMSP altitude (840 km), if the EIA is well developed (high density peaks at the EIA crests), the plasma should be transported to very high height at the equatorial region, which is difficult. For instance, if the EIA crests locate at about $\pm 10^\circ\text{N}$, the apex of the field line is about 1064 km. Though the ion density

C4

in equatorial region at DMS altitude was large, lower density at the EIA crests was normal and reasonable. It is a typo. The coordinate systems in Figure 4 and Figure 5 are geomagnetic.

-at Figure 6 why CTR is higher at day 18 compared to day 17 in the CHAMP data while CTR is higher at day 17 compared to day 18 in GRACE data if the satellite had just 90 km difference in altitude? - the authors pointed out that "the plasma bubble is preferable to occur when the EIA is symmetric" (and here some papers are referred) however on day 17 and especially on day 18 larger asymmetries (lines 230 to 232) were observed (see Figure 6) on these EIA crests when compared to days 16 and 19. As large occurrence of bubbles was observed on days 17 and 18 how the authors explain this fact?

Response: In Figure 6, the variations of EIA strength (CTR) and asymmetry (ASY) were different at CHAMP and GRACE altitude. From the variations of the EIA, we can speculate the existence of meridional wind, which may also affect the strength of EIA. The meridional wind may have the altitudinal and latitudinal gradient (Huba and Krall, 2013; Meriwether et al., 2008), thus the EIA strength and asymmetry were different at different altitudes. Generally, the plasma bubble is preferable to occur when the EIA is symmetric due to the effect of meridional wind. When the co-existence of enhanced eastward electric field and meridional wind, the competition of the two factors would be considered. On 17 and 18 August, the eastward electric fields were enhanced and lead to the occurrence of irregularities, though the EIA became asymmetric due to the meridional wind. It also means that the effects of enhancement of eastward electric field play an important role in the occurrence of irregularities, while meridional wind may not play the first important role in the occurrence of irregularities.

- at Figure 7 please clarify the white background. Is this lack of data coverage?

Response: Figure 7 is downloaded from the website (http://guvitimed.jhuapl.edu/data_products), the white background is the lack of data coverage.

- at Figure 9 is advisable to use SYM H (if available) to have more time resolution what can help to associate its variation with the other parameters. - English should be improved at some papers (below some parts are pointed out).

Response: Thanks very much for the useful suggestions. We would try to study the variations of SYM-H index and improve our writing in the text.

Minor but not less important suggestions/comments/questions are:
