Abstract. We employ JRA-55, a recent second-generation global reanalysis providing data of high-quality in the stratosphere, to examine whether a distinguishable effect of geomagnetic activity on northern hemisphere stratospheric temperatures can be detected. We focus on how the statistical significance of stratospheric temperature differences may be robustly assessed during years with high and low geomagnetic activity. Two problems must be overcome. The first is the temporal autocorrelation of the data, which is addressed with a correction of the t-statistics by means of the estimate of the number of independent values in the series of correlated values. The second is the problem of multiplicity due to strong spatial autocorrelations, which is addressed by means of a false discovery rate (FDR) procedure. We find that the statistical tests fail to formally reject the null hypothesis, i.e. no significant response to geomagnetic activity can be found in the seasonal-mean northern-hemisphere stratospheric temperature record.

10 1 Introduction

There is a large interest in the potential climate impact of geomagnetic activity. One of the main mechanisms by which geomagnetic activity is thought to affect the middle atmosphere is through the production of nitrogen oxides (NO_x 's), either by the continuous precipitation of auroral electrons penetrating into the lower thermosphere or by the more episodic precipitation of higher energy electrons into the mesosphere. Downward transport from the mesosphere to the stratosphere in winter results in increased availability of NO_x in the dark polar stratosphere, where it is long-lived. NO_x can catalytically reduce ozone concentrations as the sun returns, and thus alter radiative heating rates, with potential observable impacts on stratospheric temperatures and possible implications also for surface air temperature (SAT). The amount of NO_x in the middle atmosphere during late winter and spring depends on the cumulated effect of geomagnetic activity over the preceding months on the NO_x reservoir. Stratospheric NO_x concentrations however also depend on the magnitude of the downward transport from this reservoir, and is thereby affected by internal variability of the atmospheric circulation from year to year, especially in the Northern Hemisphere (NH).

The impact of energetic electron precipitation (EEP) driven by geomagnetic activity on NO_x and ozone concentrations has been

well-documented after detailed satellite studies were carried out in the early 2000's (Funke et al., 2005; Randall et al., 2005). Several recent studies (Baumgaertner et al., 2010; Bucha, 2014; Lu et al., 2008; Seppälä et al., 2009, 2013) suggest a significant signal associated with geomagnetic activity in the observed climate. However, there remains considerable uncertainty regarding the precise attribution of such signal, and the existence of a direct link between EEP and stratospheric temperatures has remained controversial. Among others, the study of Seppälä et al. (2009); henceforth S09, in particular, claims to find a significant, direct relationship between SAT and geomagnetic activity based on reanalysis data from the European Centre for Medium Range Weather Forecast (ECMWF). In essence, S09 finds that the hypothesis that geomagnetic activity influences the SAT is supported by reanalysis data, whereas the null hypothesis that the SAT is not influenced by the geomagnetic activity at all is rejected. S09 compares seasonal SAT in years with high and low geomagnetic activity, and also considered the separate effect of the variation in solar irradiance associated with the 11-year heliomagnetic cycle.

The selection of years in S09 was based on two indices, Ap and f10.7. Ap (Rostoker, 1972) provides a measure for daily average level of geomagnetic activity. To account for cumulative effect of NOx production, transport and diffusion processes, Ap was commonly averaged over 4 months from late autumn to winter (Seppälä et al., 2009; Funke et al., 2014; Tomikawa, 2017). In particular, S09 used Ap averaged between October and January to define winters of high and low geomagnetic activity in the northern hemisphere. The second index, f10.7 (<https://www.swpc.noaa.gov/phenomena/f107-cm-radio-emissions>), is an indicator of the phase and intensity of the solar cycle. By compositing separately on the basis of Ap and f10.7, S09 obtained different samples of seasonal-mean data for years with high geomagnetic activity and for years with low geomagnetic activity. They then computed the SAT differences of the seasonal means (DJF, MAM, JJA, SON) between the two samples, and employed a t-test based on the set of daily-means used to compute the seasonal averages to discriminate against a null hypothesis of no effect. As a consequence of such procedure, S09's claimed of significance is marred by the presence of very strong temporal and spatial autocorrelation within the samples.

In this paper, we revisit the S09 hypothesis by adopting a rigorous methodology for significance testing on strongly autocorrelated data. We focus on wintertime stratospheric temperatures between 200 hPa and 1 hPa, a pre-requisite for possible surface impacts associated with EEP-related changes in ozone concentrations. We show that statistical testing appropriate to the data at hand is a crucial step in any analysis purporting to demonstrate an observed climate signal of geomagnetic activity.

Data and methods are described in section 2, including a discussion on the problem of autocorrelation in time and space. In section 3, the results obtained by applying the t-test to the stratospheric temperatures are shown. The analysis is applied to four different cases: with no correction at all, with the temporal and the spatial autocorrelation correction applied separately, and with both the corrections applied. In Section 4 conclusions are drawn.

2 Data and Methods

2.1 Data

To analyze the possible impact of geomagnetic activity in the stratosphere, we use the Japanese 55-year Reanalysis (JRA-55) covering more than 55 years, extending from 1958 to the present (Kobayashi et al., 2005). Due to the selection of cases of high

and low geomagnetic activity as in S09, only data up to 2006 is used here. In JRA-55 reanalysis ozone is used interactively in the radiation code, although it is treated differently in the pre- and post-1979 satellite era. This is an important asset for JRA-55 since the EEP will primarily affect NO_x and ozone, and this feature is not commonly found in other reanalysis systems, such as the ECMWF reanalyses. Older generation reanalyses tend to suffer from temporal inhomogeneities because of the sequential
60 introduction of new satellite data during the assimilation period, especially in the SH as shown recently by Long et al. (2017). For these various reasons, we restricted our analysis to the recent JRA-55 reanalysis. Tomikawa (2017) also used the JRA-55 reanalyses to investigate the signature of geomagnetic activity, but focused exclusively on the SH. He found a temperature signal in the upper stratosphere, but only in July. The S09 selection shown in Table 1 is used to compute the significance of the seasonal differences. The criteria used to select the different years are based on the Ap and f10.7 values, and are the same
65 as used by S09. The definition of high and low geomagnetic activity is the same of S09. We hence investigate the potential signatures on stratospheric temperature during the same winters and in the following seasons of the same calendar year as S09 did for SAT. The set of data is denominated N1 as in S09 (Table 1).

2.2 Data autocorrelation and statistical significance

S09 computed the SAT differences of the seasonal means (DJF, MAM, JJA, SON) between those selected high Ap and low Ap
70 years, and employed the t-test (hereafter only t-test) to assess the likelihood of the differences given a null hypothesis of no effect. Such a test assumes a statistical model in which observations are normally distributed and statistically independent. In particular, the t-test is sensitive to the temporal autocorrelation or serial correlation within the samples. When serial correlation is not taken into account in the data, statistically significant differences in two means, which may not be different at all, are found more frequently than expected (Zwiers and von Storch, 1995). S09's analysis is affected by this problem, because they
75 used daily-mean data in their t-test, which are highly autocorrelated in time. As seasonal averages can still suffer from temporal autocorrelation, the serial dependence is checked by means of the Durbin-Watson test (Durbin and Watson, 1950). While the serial correlation, in general, is reduced from seasonal averaging, it can still persist, especially in summer. To deal with such serial correlation a correction is applied as suggested by Zwiers and von Storch (1995). The temporal autocorrelation is not the only potential caveat that needs to be considered when testing a hypothesis. When performing a significance test simultaneously
80 on many samples one will at some point find statistically significant points simply by accident. Unfortunately, the dominant approach to the multiplicity problem is generally to test the single grid points and then to report them as "significant" when the null hypothesis is locally rejected Wilks (2016). Sometimes temporal and spatial autocorrelation is not addressed at all. However, there are some exceptions. Maliniemi et al. (2014), for instance, trying to find a relationship between solar activity and surface air temperature dealt with temporal and spatial autocorrelation using a Monte Carlo approach. To overcome this
85 multiplicity problem in our analysis, we apply the false discovery rate controlling procedure suggested by Wilks (2016).

2.3 Accounting for temporal autocorrelation

The t-test is a widely used method for hypothesis testing within the climate community. It is however well known that the t-test, which assumes a statistical model where observations are statistically independent and Gaussian, is sensitive to time

autocorrelation or serial correlation within the samples. The effect of serial correlation is, usually, to make comparisons of means too liberal. The null hypothesis assuming equal means is hence rejected more frequently than expected.

Two separate reasons favor the use seasonal-mean data instead of daily-mean data. The first reason is that any influence of EEP on temperature is expected to accumulate over seasonal time scales. The second reason is that daily temperatures are strongly serially correlated, whereas seasonal data have less correlation between two consecutive years, for instance. Nevertheless, even for seasonal means it is important to account for serial correlations. Fig. 1 shows the results of the Durbin-Watson test (Durbin and Watson, 1950) applied at the seasonal temperatures at 5 and 10 hPa. The Durbin-Watson test is a classical test to check whether data are serially correlated. In this case, the test gives values close to zero; whereas when data are not correlated at all, the test statistic values, as a rule of thumbs, are in the range of 1.5 to 2.5. There is also the possibility of serial anti-correlation: in such a case, the value would be above 2.5, but this situation was not found in our study.

During the winter and spring seasons, the data generally do not have a very strong temporal autocorrelation, and the t-test can be applied with a lower risk of obtaining false positive outcomes. However, there are some regions where the temporal autocorrelation still persists, such as over North America. The data are very auto-correlated during the summer season, and to a large extent also in autumn, but they will be analyzed in any case as it is worthwhile as well to show how the procedure used to assess the possible impact of the geomagnetic activity responds to serially correlated data.

Serial correlation can be corrected for by adopting, for example, the strategy suggested by Zwiers and von Storch (1995). This procedure is valid under the assumption that time series, from which the data are sampled can be modeled as an autoregressive process of order 1 or AR(1). Vyushin et al. (2012) have shown that the AR(1) representation fits modeled stratospheric temperature data very well according to standard goodness of fit tests. Seidel and Lanzante (2004) found a similar result with temperature observed by radiosondes and satellites. If EEP has a cumulative impact during the different seasons, it has to be shown that the means of two subsets with high (H) and low (L) Ap values from the set N1 must be different.

To test the null hypothesis of equal means $H_0 : \mu_H = \mu_L$ with the t-statistics at the 5% significance level one let's apply the t-test under the condition that the standard deviation is scaled by the equivalent sample sizes m_e and n_e that can be computed, by:

$$n_e = n \left(\frac{1 - \rho_1}{1 + \rho_1} \right) \quad (1)$$

where n is the original size of one out of two samples and ρ_1 is the parameter of the AR(1) process representing the autocorrelation at lag 1; and similar for m_e . The t-test is then corrected in the following way:

$$t = \frac{\bar{H} - \bar{L}}{s \left(\frac{1}{\sqrt{m_e}} + \frac{1}{\sqrt{n_e}} \right)} \quad (2)$$

where \bar{H} and \bar{L} are the sample averages and s^2 is the pooled variance

$$s^2 = \frac{\sum_{i=1}^m (H_i - \bar{H})^2 + \sum_{i=1}^m (L_i - \bar{L})^2}{m + n - 2} \quad (3)$$

2.4 Accounting for spatial autocorrelation

120 Spatial autocorrelation produces the so-called multiplicity problem, which arises when testing a statistical hypothesis on many samples (the domain's grid points, in our case) simultaneously. A single hypothesis test allows for a null hypothesis against an alternative hypothesis, which will be favored when an extreme value, usually with a probability that is less than 5% is found (Wilks, 2016). Making a statistical test on multiple points, for example within a spatial domain, means that more realizations will be available and there will be many grid points where one is more likely to reject the null hypothesis. In an ideal situation, 125 where the value is set to 0.05 and each point is statistically independent of the others, it is expected to find that 5% of the points will be statistically significant by accident. The situation is worse when the grid points are correlated, as is often the case when analyzing meteorological and climate data. This problem, known in the literature as the multiplicity problem, has been encountered in several studies, although most of the studies in the atmospheric science have not properly addressed the issue yet (Wilks, 2016). Some solutions have been proposed, each having their own advantages and disadvantages. Wilks 130 (2016) gives a brief historical outline and shows different solutions to this problem. One technique to address this issue is by using the false discovery rate (Benjamini and Hochberg, 1995). According to Wilks (2006, 2016) the false discovery rate is the expectation of the fraction of true null hypothesis rejections among all the rejections and it is the best available approach to analyze multiple hypothesis test results, even when those results are mutually correlated.

According to Wilks (2016) the FDR procedure requires smaller values to reject the local null hypothesis arising the standard 135 of the test. For the sake of the reader we will describe the FDR algorithm as described in Wilks (2016). The algorithm operates on the collection of $H_0 : \mu_H = \mu_L$ values from m_e (number of grid points) local hypothesis tests p_i , with $i = 1, \dots, N$, which are sorted in ascending order. Rejection of the test happens when the p_i values are not larger than a threshold level p_{FDR} that is a function of the distribution of the sorted p_i values. More specifically to define which values pass the test the following formula is used:

140

$$\left[p_i : p_i \leq \alpha_{FDR} \left(\frac{i}{N} \right) \right]$$

where α_{FDR} is the chosen FDR control level that here is taken equal to 0.05. For a given value of α_{FDR} , the largest value of i , let's say J , such that $p_J \leq \alpha_{FDR} \left(\frac{i}{N} \right)$ defines the threshold below which the local null hypotheses are rejected.

145 3 Results

As can be seen in Fig. 2, the application of the t-test (the Welch's t-test is used here) on the stratospheric (5 and 10 hPa) temperature shows that there are large areas with significant points, at 5% level, considering a distribution with two tails, during the winter and the summer.

At 5 hPa, the area with significant points covers most of the hemisphere in JJA, but, as can be seen from the analysis of the 150 Durbin-Watson test, the summertime exhibits a large temporal autocorrelation. Hence, the significant points observed in JJA should originate from this autocorrelation. In winter, the area with significant points cover North America, another region where

the Durbin-Watson test suggests serial correlation. At 5 hPa, the area with significant points cover most of the hemisphere in JJA. It is clear from Fig. 2 that a possible impact of the geomagnetic activity would be limited at higher latitudes, from 40° to 90°. Hence, the corrections described earlier concerning the spatial and temporal autocorrelations were applied using the p-values of those latitudes since low latitudes are dominated by large statistically insignificant areas.

Thus, it is expected that at least in summer, these significant points should be false positive outcomes and they should be reduced or completely removed when applying the serial correlation correction (Fig. 3). In fact, by applying the correction of serial dependence the t-test results change dramatically, with almost all the significant points removed everywhere in JJA. However, in DJF a few significant points are still present at the 5 and 10 hPa levels. The Durbin-Watson test somehow predicted that there will be not significant points after applying the Zweirs and von Storch algorithm in the areas where the Durbin-Watson test value was close to zero.

On the other hand, the problem of multiplicity is solved here by means of the FDR procedure described in section 2. When applying such a procedure without correcting the serial dependence all the significant point at 10 hPa disappear, while some significant points still persist at 5 hPa during summertime (Fig. 4). This result is important as the FDR procedure is quite powerful in removing most of the false positive points but, clearly, it cannot be sufficient as the presence of a strong temporal correlation can still leave grid points where the t-test rejects the null hypothesis when, in fact, it would be true. The application of corrections dealing both with temporal and spatial autocorrelation removes all the significant points in the domain (not shown as it would be the same figure as Fig. 2, but with no significant points) and the combined tests fail to reject the null hypothesis. A similar conclusion is obtained with temperature differences at other stratospheric levels (not shown), ranging from 100 to 1 hPa. At those levels, the areas with significant points are even smaller than those at 5 or 10 hPa. The application of the false discovery rate on those fields eliminates all the significant points, showing that also at those levels there is no detectable impact of geomagnetic activity on the stratospheric temperature.

4 Conclusions

Climate data often exhibit temporal and spatial autocorrelations which should be taken into account when testing an hypothesis, a task that is often neglected Wilks (2016). The effect of temporal autocorrelation was addressed with an appropriate procedure described in Zwiers and von Storch (1995). The problem of evaluating results of multiple hypothesis tests in a spatial domain was further addressed by means of the false discovery rate procedure.

In this paper, the possible impact of geomagnetic activity on the seasonal-mean stratospheric temperature in the JRA-55 re-analysis was evaluated by means a Welch's t-test under four different cases: 1) with no correction of temporal and spatial autocorrelation, 2) with correction on temporal autocorrelation only, 3) with correction on spatial autocorrelation only, and finally 4) with both the corrections. Most of the cases examined show significant points when temporal and spatial autocorrelations are not corrected, while not showing any significant point when including just one out of the two corrections. In other words, in most cases, there is not even a need to apply both corrections to infer that there is no impact of geomagnetic activity. In some cases, like for the JJA temperature difference at 10 hPa (Fig. 4), there were a few significant points remaining when

185 applying one out of the two corrections, but those significant points disappeared when both corrections were applied. Thus,
when applying the procedures to take into account these autocorrelations, the significance test typically fails to reject the null
hypothesis. We therefore conclude that, based on the JRA-55 reanalyses, not enough evidence is available at present to suggest
that the null hypothesis of no impact of geomagnetic activity on NH stratospheric temperatures is false. A remaining caveat
concerns the definition of seasons of high or low geomagnetic activity, which is here the same as in S09 and is based on a
190 lagged 4-month averaged Ap index, (i.e., from October to January for wintertime geomagnetic activity). Some sensitivity stud-
ies to this definition, e.g., to treat more intense shorter episodes of EEP or to treat differently the seasonal lag or accumulation
of EEP, is certainly warranted for future studies.

Data availability. Data can be downloaded from the Meteorological Research Institute/Japan Meteorological Agency/Japan or from Re-
search Data Archive at the National Center for Atmospheric Research, Computational and Information Systems Laboratory
