Abstract. Recently the two-spacecraft mission BepiColombo launched to explore the plasma and magnetic field environment of Mercury. Both spacecraft, the Mercury Planetary Orbiter (MPO) and the Mercury Magnetospheric Orbiter (MMO, also referred to as Mio), are equipped with fluxgate magnetometers, which have proven to be well-suited to measure the magnetic field in space with high precisions. Nevertheless, accurate magnetic field measurements require proper in-flight calibration. In particular the magnetometer offset, which relates relative fluxgate readings into an absolute value, needs to be determined with high accuracy. Usually, the offsets are evaluated from observations of Alfvénic fluctuations in the pristine solar wind, if those are available. While Mio's orbit will indeed partially reside in the solar wind, MPO will remain within the magnetosphere at most times during the main mission phase. Therefore, we examine an alternative offset determination method, based on the observation of highly compressional fluctuations, the so-called mirror mode technique. To evaluate the method performance in the Hermean environment, we analyze four years of MESSENGER magnetometer data, which are calibrated by the Alfvénic fluctuation method, and compare it with the accuracy and error of the offsets determined by the mirror mode method in different plasma environments around Mercury. We show that the mirror mode method yields the same offset estimates and thereby confirms its applicability. Furthermore, we evaluate the spacecraft observation time within different regions necessary to obtain reliable offset estimates. Although the lowest percentage of strong compressional fluctuations are observed in the solar wind, this region is most suitable for an accurate offset determination with the mirror mode method. 132 hours of solar wind data are sufficient to determine the offset to within 0.5 nT, while thousands of hours are nec-

essary to reach this accuracy in the magnetosheath or within the magnetosphere. We conclude that in the solar wind the mirror mode method might be a good complementary approach to the Alfvénic fluctuation method to determine the (spin-axis) offset of the Mio magnetometer. However, although the mirror mode method requires considerably more data within the magnetosphere, it might also be
25 for the MPO magnetometer one of the most valuable tools to determine the offsets accurately.

1 Introduction

In October 2018, BepiColombo, a two-spacecraft mission of the European Space Agency (ESA) and the Japan Aerospace Exploration Agency (JAXA), was launched to explore Mercury (Benkhoff et al., 2010). One of the spacecraft is the Mercury Planetary Orbiter (MPO), which is a 3-axis
30 stabilized satellite (quasi nadir pointing) to study the surface and interior of the planet (e.g. Glassmeier et al., 2010). The other is Mio (or Mercury Magnetospheric Orbiter, MMO), a spin-stabilized spacecraft (spin period of about 4 s) to investigate the magnetic field environment of Mercury (e.g. Hayakawa et al., 2004; Baumjohann et al., 2006). During the 7.2 year cruise phase, both orbiters are transported by the Mercury Transfer Module (MTM) as a single composite spacecraft. In late
35 2025, the composite spacecraft will approach Mercury, where the MTM separates from the other two spacecraft, which are captured into a polar orbit around the planet. As soon as Mio reaches its initial operational orbit of 590 km by 11640 km above the surface, also MPO separates and lowers its altitude to its 480 km by 1500 km orbit.

40 The BepiColombo Mercury Magnetometers (MERMAG) constitute a key experiment of the mission; MERMAG consists of the fluxgate magnetometers onboard both, MPO and Mio. The magnetometers will provide in-situ data for the characterization of the internal field origin as well as its dynamic interaction with the solar wind (see e.g. Wicht and Heyner, 2014, for a discussion). To achieve this goal, accurate magnetic field measurements are thus of crucial importance. Therefore,
45 the components of a linear calibration matrix $\underline{\mathbf{M}}$ and an offset vector \mathbf{O} need to be obtained, in order to convert raw instrument outputs \mathbf{B}_{raw} to fully calibrated magnetic field measurements (see e.g. Kepko et al., 1996; Plaschke and Narita, 2016):

$$\mathbf{B} = \underline{\mathbf{M}} \cdot \mathbf{B}_{\text{raw}} - \mathbf{O}. \quad (1)$$

Here, the matrix $\underline{\mathbf{M}}$ transforms \mathbf{B}_{raw} into a spacecraft-fixed orthogonal coordinate system. It comprises 9 parameters: 3 scaling (gain) values of the sensor and an orthogonalization matrix, which is
50 defined by the 6 angles that yield the magnetometer sensor directions with respect to the spacecraft reference frame (see e.g. Plaschke and Narita, 2016). The 3-D offset vector \mathbf{O} , on the other hand, reflects the magnetometer outputs in vanishing ambient fields. These can be attributed to the instrument and also to the field generated by the spacecraft at the position of the magnetometer sensor.
55 Frequent in-flight calibration of these offsets is necessary, as they are known to change over time.

To calibrate the magnetometer, all 12 parameters need to be accurately determined. For spinning spacecraft (i.e. Mio) 8 of the calibration parameters can be determined directly by minimizing periodic signatures in the de-spun magnetic field signal at the spin frequency and/or at the second harmonic (Kepko et al., 1996). The remaining 4 parameters i.e. the absolute gain in the spin-plane and along spin-axis, the rotation angle of the sensor around the spin-axis, and the spin-axis offset need to be determined differently. It should be noted that the gains and rotation angle become important at strong fields. In the solar wind and in the Hermean environment they may play a minor role in the magnetic field measurements accuracy in comparison to the offsets.

The following methods, which can also be applied to non-spinning spacecraft (i.e. MPO), are well established for the offset determination: (1) Cross-calibration of the magnetometer offset with independent magnetic field measurements from other instruments. The Magnetospheric Multiscale mission (MMS, Burch et al., 2016) use independent measurements from the Electron Drift Instruments (EDI, Torbert et al., 2016) to cross-calibrate the spin-axis offset of the magnetometers (Nakamura et al., 2014; Plaschke et al., 2014)). (2) The offset may also be determined in a characteristic region where the magnetic field is known. Goetz et al. (2016) used diamagnetic cavities to determine the magnetometer offsets of the Rosetta spacecraft mission (Glassmeier et al., 2007). (3) The most common way to calibrate the offset in-flight, is to use well-known fluctuations of the magnetic field observations. An established method is to minimize the variance of the total magnetic field during the passage of incompressible (Alfvénic) variations in the (pristine) solar wind (Belcher, 1973; Hedgecock, 1975). Recently Plaschke and Narita (2016) introduced the so-called mirror mode method to determine the magnetometer offset on the basis of compressible fluctuations. This method does not require pristine solar wind measurements. The idea is that for strongly compressible fluctuating fields (e.g. mirror modes) the maximum variance direction should be nearly parallel to the mean (background) magnetic field (Tsurutani et al., 2011). Any differences between these two directions can thus be evaluated and used for offset determination. An advantage of this method is that compressible waves are ubiquitous in the magnetosphere and magnetosheath. Therefore this method can also be applied to calibrate the magnetometers of spacecraft which remain within the magnetosphere (like e.g. MPO).

85

In this paper we test the applicability of the mirror mode method in different regions (plasma environments) around Mercury, based on 4-years of MESSENGER (MErcury Surface, Space ENvironment, GEophysics and Ranging, Solomon et al., 2007) fluxgate magnetometer data (FGM, Anderson et al., 2007), which were calibrated using time intervals of incompressible Alfvénic fluctuations in the solar wind. For reasons of simplicity (and because for Mio only the spin-axis offset needs to be determined) we apply the 1-D mirror mode method (see Plaschke and Narita, 2016) and test to which degree it yields vanishing offsets as expected when using calibrated data as input. We

90

also address the question of how much time Mio and MPO need to spend in each individual plasma region until the magnetometer offset can be determined to a specific accuracy from intervals containing compressional magnetic field fluctuations.

The results obtained in this paper enable us to assess whether the mirror mode method would be an useful tool to accurately determine the offset of BepiColombo's magnetometer.

2 Data and Methodology

We use orbital magnetic field data from the MESSENGER fluxgate magnetometer (FGM, Anderson et al., 2007) between March 2011 and April 2015. The polar orbit of MESSENGER is highly elliptical; initially altitudes ranges between 200 km and 15000 km from Mercury's surface. With an initial orbital period of 12 hours, MESSENGER crosses the magnetopause and bow shock four times within 24 hours. We use the 1-Hz calibrated magnetic field data in spacecraft coordinates, where the Y -axis is nominally in the anti-sunward direction (radially away from the Sun), the Z -axis points towards the payload adapter ring at the bottom of the spacecraft, and the X -axis completes the right handed coordinated system. If not noted otherwise, we use the magnetic field components $\{B_x, B_y, B_z\}$ throughout this paper in these coordinates. MESSENGER is a three-axis-stabilized spacecraft, and its magnetometer offsets are routinely corrected using time intervals of Alfvénic fluctuations in the solar wind. We therefore use the MESSENGER magnetometer data as a calibration standard in our magnetometer offset study. To perform a test of the the mirror mode method against the MESSENGER magnetometer data, we determine the 1D offset along the Z -axis, O_z , in the same way as introduced by Plaschke and Narita (2016):

Within strongly compressible mirror mode structures, the magnetic field variation maximum variance direction, $\ell = [l_x, l_y, l_z]$ obtained from a principal component analysis (minimum variance analysis (MVA, Sonnerup and Scheible, 1998)) should be reasonably aligned with the mean field direction, $\mathbf{B} = [B_x, B_y, B_z]$. Under assumption of alignment between the maximum variance direction and the mean field direction Plaschke and Narita (2016) showed that the offset O_z can be derived by:

$$O_z = B_{xy}(\tan\theta_B - \tan\theta_\ell), \quad (2)$$

where $\theta_B = \arctan(B_z/B_{xy})$ is the elevation angle of magnetic field to the XY -plane and $\theta_\ell = \arctan(l_z/l_{xy})$ the elevation angle of the maximum variance direction to that plane. $B_{xy} = \sqrt{B_x^2 + B_y^2}$ and $l_{xy} = \sqrt{l_x^2 + l_y^2}$ are the magnetic field and maximum variance within the XY -plane.

Since a single offset estimate alone might not be very accurate, a statistically significant offset O_{zf} should be determined by finding the maximum of the probability density function P computed by the kernel density estimator (KDE) method with Gaussian kernel from a sample of individual offset

estimations O_z :

$$P(O_z^*) = \frac{1}{\sqrt{2\pi}Nh} \sum_{n=1}^N \exp \left[-\frac{1}{2} \left(\frac{O_z^* - O_{z,n}}{h} \right)^2 \right]. \quad (3)$$

Here N denotes the number of individual offset estimates, $O_{z,n}$. h is a smoothing parameter which
130 denotes the bandwidth of the KDE, and O_{zf} is the offset value at which the probability P is at maximum, $\max(P(O_z^*)) = P(O_{zf})$. We use the method introduced by Silverman (1986), to determine an optimal bandwidth $h = c_1 \cdot \sigma(O_{z,n})N^{c_2}$, with $c_1 = 1.06$ and $c_2 = -1/5$. The symbol σ denotes the standard deviation of the offset-value distribution.

3 Data Analysis and Results

135 A basic condition for the mirror mode method, is the availability of compressional magnetic field fluctuations. As a first step we use the magnetometer data to estimate the occurrence rate of compressional fluctuations in the different plasma environments around Mercury. Then we compare the offset determination by the mirror mode method with the Alfvén wave method in terms of accuracy. Finally, we evaluate the number of offset samples that are sufficient for in-flight calibration
140 with the mirror mode method, given a minimum required accuracy. Therewith, we subsequently determine how many hours the spacecraft (i.e. Mio and/or MPO) need to spend in different plasma environments to obtain reliable offset values.

3.1 Occurrence rate of compressional fluctuations

Mercury's plasma environment is highly dynamic and home to a plethora of wave modes and fluctuations (Russell, 1989; Boardsen et al., 2009, 2012; Sundberg et al., 2015). We separate the MESSENGER orbit segments into solar wind, magnetosheath and magnetospheric parts, based on an extended boundary data set (Winslow et al., 2013, and personal communication with R. Winslow and B. J. Anderson), in order to distinguish occurrence rates of (compressional) fluctuations and offset estimate accuracies by region. We characterize the observed fluctuations in the following way:
150 The magnetic field data are divided into overlapping 30-s intervals shifted by 15-s. Within each sub-intervals the magnetic field measurements are transformed into a mean-field-aligned (MFA) coordinate system. Then the maximum variance direction, ℓ , of the transverse (perpendicular) magnetic field components is evaluated by a 2D minimum variance analysis (MVA, Sonnerup and Scheible, 1998). The difference between the maximum and minimum values of the magnetic field in this maximum variance direction yields the measure for the transverse fluctuations $\delta B_{\perp,\ell} = B_{\perp,\ell}^{\max} - B_{\perp,\ell}^{\min}$.
155 The compressional fluctuations, on the other hand, are essentially represented by fluctuations in the magnetic field magnitude $\delta|B|$, given by the difference between the maximum and minimum value of the magnetic field magnitude within the 30-s interval. Subsequently, to determine whether the compressional or the transverse part is dominating, we further define the compressibility index Q^{\pm}

160 as

$$Q^{\pm} = \log_{10} \left(\frac{\delta|B|}{\delta B_{\perp,\ell}} \right), \quad (4)$$

which is positive/negative in case of dominating compressional/transverse fluctuations.

Left panel of Figure 1 displays the occurrence rate (normalized to unity when integrated over the whole domain) of fluctuation of the magnetic field magnitude (compressible sense) relative to the mean field in various plasma regions: in the solar wind (in red), in the magnetosheath (in green), and in the Hermean magnetosphere (in blue) for the MESSENGER magnetometer data for 4 years. Most of the large-amplitude fluctuations are observed in the magnetosheath. Such a result is not surprising, since the magnetosheath is characterized generally by a highly turbulent plasma with enhanced magnetic field variations. The right panel shows the normalized occurrence rate of the compressibility index Q^{\pm} of selected intervals with large amplitude fluctuations ($\delta|B|/\bar{B} > 0.3$). The shifts of the maximum occurrence rates to negative Q^{\pm} values indicate that statistically transverse fluctuations were dominating. However, there is also a significant number of time intervals with compressional fluctuations observed. The integrated occurrence rates are shown in Table 1. The first column of Table 1 shows the percentage of the sub-intervals where the magnetic field magnitude fluctuations $\delta|B|/\bar{B}$ were larger than 0.3. The percentage in the second column shows how many of the intervals with large-amplitude fluctuation ($\delta|B|/\bar{B} > 0.3$) are dominated by strongly compressional fluctuations, where $\delta|B|/\delta B_{\perp,\ell} > 2$ ($Q^{\pm} > 0.3$). The last column reflects the percentage of intervals that include these strongly compressional fluctuations out of all intervals of MESSENGER observations in the respective regions.

About 25 % of the time enhanced magnetic field fluctuations ($\delta B/\bar{B} > 0.3$) are observed in the magnetosheath and 10.6 % of these fluctuations had a compressional nature. That means that from the total observation time in the magnetosheath, 2.6 % of the time MESSENGER observed strongly compressional fluctuations. A smaller fraction of the MESSENGER data set represent compressible dominated time intervals of the solar wind (0.4 %) and the Hermean magnetosphere (1.7 %). This suggests that the MESSENGER magnetosheath data may be best suited for the offset calibration with the mirror mode method.

3.2 Test of the mirror mode method

Using Equation 2 we determine the offset O_z within each 30-sec time interval. To ensure reliable offset estimates, the same requirements introduced by Plaschke and Narita (2016) have to be fulfilled within each window:

$$-\frac{\delta B_{xy}}{\bar{B}_{xy}} = \frac{B_{xy}^{\max} - B_{xy}^{\min}}{B_{xy}^{\text{mean}}} > 0.3, \text{ since mirror modes are characterized by large magnetic field fluctuations (see Price et al., 1986; Schmid et al., 2014). } B_{xy}^{\max}, B_{xy}^{\min} \text{ and } B_{xy}^{\text{mean}} \text{ are the maximum, minimum and average magnetic field values in the spacecraft } XY\text{-plane, respectively.}$$

195 Note that we only consider the XY -plane components, because the Z -component are subject to an a-priori unknown offset O_z .

– $\phi < 20^\circ$, where ϕ is the angle between the maximum variance, ℓ , and magnetic field, \mathbf{B} , directions in the XY -plane. Note that only the XY -plane components is used. Plaschke and Narita (2016) derived this requirement and threshold from (Lucek et al., 1999), who identified
200 mirror modes due to the angle between maximum variance and magnetic field direction.

– $|\theta_B| < 30^\circ$ and $|\theta_\ell| < 30^\circ$, so that both, maximum variance and magnetic field directions point closer to the XY -plane.

Out of 4-years of MESSENGER data these requirements are met for 3.0 %, 2.1 % and 0.4 % of the intervals within the magnetosphere, magnetosheath and the solar wind, respectively (see also first
205 column of Table 2). It should be noted that these numbers do not have to match the numbers shown in Table 1, since the criteria are different. The numbers in Table 1 reflect the occurrences of strongly compressional fluctuations and here they reflect the occurrences of intervals with mirror mode like characteristics. Interestingly, however, the numbers in the solar wind and the magnetosheath are similar but differ considerably in the magnetosphere.

210 Using Equation 3 the probability density function P is computed for each region from all determined best-estimate offset O_z in that region. Under the assumption that the data are perfectly calibrated and the mirror mode method works accurately, the offset O_{zf} should vanish and P should be highly symmetric with the peak around 0 nT.

Figure 2 shows the probability density functions P based on the magnetosphere (red), magne-
215 tosheath (green) and solar wind (blue) offset estimates. Indeed, the best estimate of the Z -component offset O_{zf} is around zero for all three regions. It is noteworthy that the standard deviation of individual offset estimates, $O_{z,n}$, is smallest in the solar wind. This is actually not surprising, since the intervals in the solar wind where the above requirements are fulfilled, are well-suited for this calibration method due to their clear compressional signature in the rather low background magnetic
220 field. In Table 2 the total number of intervals (O_z estimates) and their best-estimate offset O_{zf} are given. Further, the arithmetic mean of the individual offsets in each interval $O_{z,n}$ with their standard deviations and error are summarized.

The average $\langle O_{z,n} \rangle$ is found to be quite close to the final offset estimate O_{zf} . Note that, although
225 the standard deviation of the individual offsets $O_{z,n}$ might be large, a larger number of samples or events helps lower the value of the standard deviation of the mean offset $\langle O_{z,n} \rangle$ (standard error in Table 2).

3.3 Effect of sample size on offset accuracy

In the following we check how the best-estimate offset O_{zf} is affected by the number of $O_{z,n}$ estimates. Therefore, from each region, 1 to 20000 offset estimates ($N = \{x \cdot 10^y \mid x \in [1, 9], y \in [0, 4]\}$, $\max(N) = 20000$) are randomly picked and their best-estimate offset O_{zf} determined. For each N , this sequence is repeated 1000 times (bootstrapping). The standard deviation of the 1000 O_{zf} ($\sigma(O_{zf})$) subsequently reflects the uncertainty of the determined O_{zf} . Here we use the $2\text{-}\sigma$ interval, to evaluate the uncertainty of the best-estimate offset O_{zf} with 95 % confidence. The standard error ϵ of the $2\text{-}\sigma$ uncertainty of the best-estimate offset, $2\text{-}\sigma(O_{zf})$, from the bootstrapping is given by $\epsilon \simeq 2\text{-}\sigma(O_{zf})/\sqrt{2(M-1)}$ (see e.g. Squires, 2001). Here $M = 1000$ yielding a relative standard error $\epsilon = 4.3\%$ of the evaluated $2\text{-}\sigma(O_{zf})$. Figure 3 displays $2\text{-}\sigma(O_{zf})$ as a function of the number N of the offset estimates $O_{z,n}$ used.

The dashed lines in Figure 3 mark offset accuracies at 0.5 nT and 1.0 nT. It is visible that the offset accuracy increases with the number of samples following a power law. However, below ~ 0.5 nT considerably more samples are needed to improve the offset accuracy, which could indicate the lower limit of the offset accuracy of the MESSENGER magnetometer determined by the Alfvénic method. As can be seen in Figure 3, this divergence is only observed in the solar wind, because it is the only region where a significant number of $O_{zf} < 0.5$ nT are obtained. The solid lines in Figure 3 depict the regression lines of a linear least squares fit of the offset accuracies above 0.5 nT and clearly shows the power law behavior between these offset accuracies and the number of samples. Table 3 shows the fitting parameters of the regression lines of the power laws,

$$\log_{10}[2\sigma(O_{zf})] = \log_{10}[a] + k \cdot \log_{10}[N]. \quad (5)$$

Here a denotes the $2\text{-}\sigma$ confidence of the best-estimate O_{zf} determined from only one offset O_z and k represents the spectral index of the power law.

From the least squares approximation we calculate the minimum number N of $O_{z,n}$ estimates to reach an offset accuracy of 0.5 nT and 1.0 nT. These numbers are multiplied by 30 s, the sliding window time interval, yielding the time ranges from which reliable $O_{z,n}$ estimates are obtained (i.e. where the criteria from above are satisfied). These time ranges multiplied with the probability to observe these time intervals (see first column in Table 2), finally give the time lengths that a spacecraft needs to spend in the solar wind, magnetosheath or magnetosphere in order to determine the offset with an accuracy better than 0.5 nT or 1.0 nT. Table 4 shows the minimum number N of $O_{z,n}$ estimates with their corresponding time ranges and the necessary spacecraft observation time, required to reach these accuracies.

While 132 hours of solar wind data are sufficient to determine the offset at an accuracy of 0.5 nT, 4241 hours are needed in the magnetosphere and more than 6130 hours in the magnetosheath. This is an interesting result, since the magnetosheath is the region with the highest probability to observe large-amplitude compressional fluctuations and the solar wind with the lowest (see Table 1). A

possible explanation might be that the solar wind data are observations in the shock-upstream region
265 in which the shock-reflected backstreaming ions excite large-amplitude Alfvén waves that either
pitch the plasma (through ponderomotive force) or develop into magnetosonic-type waves. However,
the results suggests that the fluctuations in the solar wind, although observed less often, are better
suited to determine the offset with the mirror mode method.

4 Discussion and Conclusions

270 We find that the offset determination method proposed by Plaschke and Narita (2016) is well ap-
plicable to the data from the Hermean environment. It can hence be used for in-flight calibration
of the magnetometers onboard Mio and MPO. The results reveal that the solar wind is the most
suitable region to accurately determine the offset by the mirror mode method, although the lowest
percentage of highly compressible fluctuations are observed there (see Table 1). As is been seen in
275 Table 4, offset determination with uncertainties better than 0.5 nT can be achieved with less than 132
hours of solar wind data. However, it is important to note that during this time the instrument offsets
need to stay constant to within 0.5 nT, otherwise the intrinsic offset drifts over time would limit
the achievable precision, independently from the the amount of solar wind data. Specifically in the
magnetosheath and within the magnetosphere this might be a more important limiting factor, since
280 several thousands of hours of data in those regions are needed to ensure that the offset uncertainty
is less than 0.5 nT (see Table 4). Figure 3 shows that the offset accuracies down to 0.5 nT diminish
with the number of necessary O_z estimates and follows a power law. However, below 0.5 nT the
power law correlation flattens (spectral index becomes smaller), which might indicate that the lower
limit of the offset accuracy of the calibrated magnetometer data itself has been reached. To ensure
285 e.g. the offset uncertainty to be of the order of 1.0 nT, 60 hours of magnetic field data in the solar
wind would be sufficient, but hundreds of hours of magnetosheath or magnetosphere data are would
be needed.

In the following we consider possible implications of these results on the BepiColombo mission:

– **Mio (Mercury Magnetospheric Orbiter, MMO):** Since Mio's orbit allows the spacecraft
290 encounter the solar wind (particularly near Mercury's perihelion), the mirror mode method
would serve as a reasonable complementary approach to the Alfvénic fluctuation method.
Furthermore, Mio is a spin-stabilized spacecraft (with a period of about 4 s) and thus two of
the three offsets in the de-spun plane can be directly determined by minimization of spin-tone
in the data. Since the two spin-plane offsets can be determined very accurate (Kepko et al.,
295 1996), the mirror mode method can determine the remaining offset (spin-axis offset) very pre-
cisely (see, Plaschke and Narita, 2016). However, the mirror mode method assumes the time
independence of the offset properties during the fluctuation measurements. Offsets drifts over
time, e.g. due to temperature changes over orbital periods, will be the limiting factors for the

achievable accuracies.

300

– **MPO (Mercury Planetary Orbiter):** The orbit of MPO, on the other hand, will remain in the Hermean magnetosphere for most of the time (except for cusp crossings or during events of high dynamic pressure in the solar wind). Based on the results obtained from MESSENGER, 780 hours of observations are needed in order to determine the offset with an accuracy better than 1.0 nT in this region. Note that during this long observation period the magnetometer offsets need to stay constant within 1.0 nT, as mentioned above. Furthermore, the MPO spacecraft is 3-axis stabilized, which should diminish the offset determination accuracy due to the two additional degrees of freedom. Hence, the 3D mirror mode method developed by (Plaschke et al., 2017) should be applicable to MPO.

305

310 From the results obtained in this work we conclude that in the solar wind the mirror mode method should be an good complementary approach to the Alfvénic fluctuation method to determine the spin-axis offset of the Mio magnetometer. In case of MPO, however, considerably more data are needed to reach the same offset accuracy, since the orbit nominally remains within Mercury’s magnetosphere. Nevertheless, the mirror mode method might still be one of the most valuable tools to
315 obtain reliable offset estimates also for the magnetometers of MPO-MAG.

Data availability The MESSENGER magnetic field (MAG) data are obtained from the NASA Planetary Data System (PDS). All data are open access and can be retrieved on the PDS website (<https://pds-ppi.igpp.ucla.edu>, NASA Planetary Date System, 2015).

Author contributions DS initiated this study, collected the data and did the analysis. FP wrote
320 the initial version of the Mirror Mode Method program and helped interpreting the results. YN evaluated the manuscript and also helped interpreting the results. WB, AM, DH and JM also assisted in evaluating the manuscript. As the PI of the MESSENGER magnetometer, BA guaranteed the quality and usability of the data.

Competing interests The authors declare that they have no conflict of interest.

Tables

Table 1. The first column gives the percentage of the sub-intervals where the magnetic field magnitude fluctuations $\delta|B|/\bar{B}$ is larger than 0.3 in each respective region. The percentage in the second column shows how many intervals of the sub-intervals with $\delta|B|/\bar{B} > 0.3$ are dominated by compressional fluctuations ($Q^\pm > 0.3$). The last column reflects the percentage of compressional fluctuations MESSENGER observes in total in each region.

Region	$\delta B /\bar{B} > 0.3$		compressible fluctuations in total
	total	$Q^\pm > 0.3$	
Solar wind	7.9 %	5.4 %	0.4 %
Magnetosheath	24.6 %	10.6 %	2.6 %
Magnetosphere	8.0 %	21.6 %	1.7 %

Table 2. Number of samples (time intervals) used in the statistical study for the offset determination and various offset estimates in units of nT (best-estimate, mean, standard deviation, and standard error).

Region	Number of samples (% of total)	best-estimate O_{zf} [nT]	mean $\langle O_{z,n} \rangle$ [nT]	standard deviation $\sigma(O_{z,n})$ [nT]	standard error $\sigma(O_{z,n})/\sqrt{N}$ [nT]
Solar wind	21200 (0.4 %)	-0.04	-0.10	6.5	0.04
Magnetosheath	29289 (2.1 %)	-0.17	-0.34	14.0	0.08
Magnetosphere	36652 (3.0 %)	-0.01	-1.01	12.4	0.09

Table 3. Fitting parameters of Equation 5 with 95 % confidence intervals, exhibited from linear least squares fit of the offset accuracies above 0.5 nT in Figure 3. a is the $2\text{-}\sigma$ confidence of the best-estimate O_{zf} determined from only one offset O_z and k is the spectral index of the power law.

Region	a [nT]	k
Solar wind	18.6 ± 1.1	-0.87 ± 0.03
Magnetosheath	34.8 ± 1.0	-0.44 ± 0.01
Magnetosphere	25.9 ± 1.0	-0.41 ± 0.01

Table 4. Minimum number of $O_{z,n}$ estimates (first row) and corresponding time ranges (second row) required to determine the offset with an accuracy of 0.5 nT or 1.0 nT in the solar wind, magnetosheath or magnetosphere. The necessary observation time of the spacecraft (third row) in each region.

Offset accuracy	Solar Wind		Magnetosheath		Magnetosphere	
	0.5 nT	1.0 nT	0.5 nT	1.0 nT	0.5 nT	1.0 nT
minimum number of samples	63	29	15325	3173	15422	2837
time to reach accuracy	31 min	14 min	128 h	26 h	128 h	24 h
necessary S/C observation time	132 h	60 h	6130 h	1269 h	4241 h	780 h

Figure Captions

Fig. 1. Left: Normalized occurrence rate of the total magnetic field fluctuations $\delta|B|/\bar{B}$ in the solar wind (blue), magnetosheath (green) and magnetosphere (red) during 4 years of MESSENGER observations. Right: Normalized occurrence rate of the compressibility index Q^\pm for magnetic fluctuations with $\delta|B|/\bar{B} > 0.3$. Positive or negative Q^\pm values indicate whether the compressional or the transverse part of the magnetic fluctuations is dominating and $Q^\pm > 0.3$ values are considered as strong compressional fluctuations.

Fig. 2. Probability density function P , estimated with the KDE method from Equation 3 from 4-years of MESSENGER observations.

Fig. 3. The relationship between $2\text{-}\sigma(O_{zf})$ as a function of the number N of the offset estimates $O_{z,n}$. $2\text{-}\sigma(O_{zf})$ is the uncertainty of the determined best-estimate offset O_{zf} with 95 % confidence. The solid lines represent the linear least squares fits of the $2\text{-}\sigma$ confidence offsets above 0.5 nT.
