Abstract. We use a newly developed global Hall MHD code to investigate how reconnection drives magnetotail asymmetries in small, ion-scale magnetospheres. Here, we consider a magnetosphere with a similar aspect ratio to Earth but with the ion inertial length (δ_i) artificially inflated by a factor of 70: δ_i is set to the length of the planetary radius. This results in a magnetotail width on the order of $30 \delta_i$, slightly smaller than Mercury’s tail and much smaller than Earth’s with respect to δ_i . At this small size, we find that the Hall effect has significant impact on the global flow pattern, changing from a symmetric, Dungey-like convection under resistive MHD to an asymmetric pattern similar to that found in previous Hall MHD simulations of Ganymede’s subsonic magnetosphere as well as other simulations of Mercury’s using multi-fluid or embedded kinetic physics. We demonstrate that the Hall effect is sufficient to induce a dawnward asymmetry in observed dipolarization front locations and find quasi-periodic global scale dipolarizations under steady, southward solar wind conditions. On average, we find a thinner current sheet dawnward; however, the measured thickness oscillates with the dipolarization cycle. During the flux-pileup stage, the dawnward current sheet can be thicker than the duskward sheet. This could be an explanation for recent observations that suggest Mercury’s current sheet is actually thicker on the duskside: a sampling bias due to a longer-lasting “thick” state in the sheet.

15 1 Introduction

In the magnetospheres of Mercury and Earth, observations of plasmoids, flux bundles, and dipolarization fronts (DFs) demonstrate a marked asymmetry in their distribution across the magnetotail. At Earth, a number of studies have found magnetotail duskward biases in several magnetic phenomena: flux rope occurrence (Slavin et al., 2005; Imber et al., 2011), dipolarization fronts (Liu et al., 2013), energetic particle injections (Gabrielse et al., 2014), and reconnection (e.g. Asano et al. (2004); Genestreti et al. (2014)). Additionally, the current sheet was found to be thinner on the duskside (Artemyev et al., 2011; Vasko et al., 2015). Similarly, at Mercury, Poh et al. (2017b) used MESSENGER data to fit the Harris sheet model to 234 tail current sheet crossings and found a bias towards dusk having thinner current sheets (by $\approx 10 - 30\%$). In contrast, however, other

MESSENGER studies (Sun et al., 2016; Dewey et al., 2018) found dawnward biases in dipolarization events and reconnection front locations.

25 The general existence of tail asymmetry is thought to be a result of sub-ion-scale effects (Lu et al., 2018; Liu et al., 2019), though there is still some uncertainty about the exact manifestation and causes of specific asymmetries. It is debated whether Hall electric fields are sufficient to reproduce this or if other ion/electron scale physics are required. Although some authors argue that electron-scale physics is required (Chen et al., 2019), we show in this paper that Hall effects are sufficient to cause an asymmetry in some observed features. Furthermore, it is unknown exactly why Mercury and Earth observe different asymmetries; it is hypothesized that system size effects (relative to the ion inertial length δ_i) play a key role (Lu et al., 30 2016, 2018; Liu et al., 2019).

Several studies have proposed mechanisms to explain how Hall reconnection induces asymmetry in the magnetotail. Lu et al. (2016, 2018) (hereafter: Lu+), in studying Earth’s magnetotail with global hybrid simulations and localized PIC simulations, showed that the decoupling of ions and electrons within the current sheet (the Hall effect; e.g. Sonnerup (1979)) creates an 35 electric field and associated tail current density. The resulting $\mathbf{E} \times \mathbf{B}$ drift is sufficient to create tail asymmetries and indeed may be the primary cause. The duskside magnetic flux is preferentially evacuated via electron transport dawnward, which leads to a smaller normal B_z and thinner current sheet on the duskside.

In a similar study, Liu et al. (2019) (hereafter: Liu+), using local PIC simulations of embedded, thin current sheets, confirmed that the Hall effect creates electron $\mathbf{E} \times \mathbf{B}$ and diamagnetic drifts which transport magnetic flux dawnward within the current 40 sheet. However, they found that, although the pre-existing tail B_z initially suppresses the onset of dawnside reconnection, the reconnection B_z drives outflows towards dawn and thins out the current sheet on that side. This creates an “active region” of reconnection on the dawn side, which has a thinner current sheet and stronger tail current j_y . After analyzing both these studies, Liu+ proposed that, although the Lu+ model provides a explanation for a duskward bias in the *initial* reconnection onset, the Liu+ “active region” provides an explanation for dawnward biases within local, in-progress magnetotail reconnection. We test 45 several aspects of this general picture within this paper.

Unfortunately, simulating large magnetospheres such as Earth (few hundred δ_i) while properly resolving the small-scale Hall physics requires grid sizes in the billions of cells. Several strategies have been proposed to evade this constraint; one is to embed regions of detailed kinetic physics within large-scale Hall MHD simulations (Chen et al., 2019). This allows for reproduction of kinetic effects within certain regions of the magnetosphere without having to run an expensive, fully kinetic 50 simulation. However, these simulations assume no kinetic effects outside the embedded regions, which are limited to certain regions in the dayside and/or the tail. It is unclear whether or not this methodology, including boundary handling, affects the local-global feedback dynamics in the magnetosphere. Future studies will eventually be needed to compare magnetospheres from Hall MHD, kinetic, and combined kinetic-Hall simulations to ascertain these effects.

Another strategy suggests that we need only set the Hall scale to some length sufficient to capture the essential physics 55 of Hall reconnection without having to fully resolve the physical length scale. In these simulations, the Hall length is set to $\approx 3\%$ of the global scale length (Tóth et al., 2017) which is sufficient to capture the out-of-plane flows and the quadrupolar magnetic field structure induced by the Hall effect. However, recent research in 2D island coalescence (Bard and Dorelli, 2018)

suggests that although including the Hall term in MHD simulations is sufficient in itself to generate these signatures of Hall reconnection, the actual reconnection rate depends on resolution and numerical resistivity. Although the Hall term is present, the reconnection itself may be Sweet-Parker-like and slow (unlike fast Hall reconnection). Bard and Dorelli (2018) observed that 20-25 cells per δ_i was necessary (within the context of their numerical viscosity) in order to observe fast Hall reconnection. This is much greater than the 5 – 10 cells per δ_i typically used in simulations (Dorelli et al., 2015; Dong et al., 2019; Chen et al., 2019). This suggests that, although artificially inflating δ_i allows the Hall effect to emerge and have a global impact, much higher resolution is required to observe the universally fast ($\sim 0.1 v_A$) reconnection observed in kinetic simulations. Finally, Bard and Dorelli (2018) found qualitatively different behavior for varying ratios of system size to δ_i : large systems can produce bursty reconnection (with a low average reconnection rate) even when δ_i is sufficiently resolved to produce “fast”, instantaneous reconnection. Ultimately, the combined requirements of high resolution and large system size creates a computational requirement beyond what is currently possible for magnetospheres. Indeed, we are only setting a resolution appropriate to 5 cells/solar wind δ_i in this work, though local density fluctuations in the tail may allow up to 10-20 cells/ δ_i .

One possible method for dealing with this issue may be to use graphics processing units (GPUs), which have proven to be robust and viable for scientific computing. Indeed, several groups have already utilized GPUs to accelerate plasma simulations throughout heliophysics, astrophysics, and plasma physics (Bard and Dorelli, 2014; Benítez-Llambay and Masset, 2016; Fatemi et al., 2017; Bard and Dorelli, 2018; Schive et al., 2018; Grete et al., 2019; Liska et al., 2019; Wang et al., 2019). GPUs take advantage of parallelism in order to have a higher throughput for floating point operations. Finite-volume schemes are massively parallel: the calculation of how a computational cell evolves from t to $t + \Delta t$ is independent of similar calculations for other cells. This makes explicit Hall MHD schemes (such as presented in this paper) quite amenable to GPU acceleration.

In this paper, we undertake a numerical experiment designed to assess the role of the Hall effect on global magnetospheric structure and dynamics within a “small” ion-scale magnetosphere, specifically focusing on how it induces asymmetry in the magnetotail. We present a magnetosphere simulation code which accelerates the explicit MHD solver algorithm via GPUs. We simulate an Earth-like analogue magnetosphere which has a similar bow shock-magnetopause distance and magnetotail width as Earth’s (relative to the planetary radius); however, δ_i is artificially inflated to the planetary radius (R_E). In other words, we are self-similarly scaling Earth from its current size relative to ion scales (magnetotail width $\approx 600\delta_i$) to a size closer to the ion scale (magnetotail width $\approx 30\delta_i$). In this “ion-scale Earth”, Hall physics plays a greater role in magnetosphere dynamics and we are able to more readily observe global Hall MHD effects. We view this work as a first step in the study of the system-size dependence of Hall MHD magnetic reconnection in Earth-like magnetospheres; future system-size studies can be performed by making δ_i smaller relative to the planetary radius and increasing the resolution to sufficiently cover the ion scales.

This paper is presented as follows: Section 2 provides a brief overview of the Hall MHD algorithm as implemented using GPUs; Section 3 provides the initial condition and setup of the simulation; Section 4 presents tail asymmetries in the simulation and discusses them in the context of observations and proposed theoretical explanations.

We take a Hall MHD code accelerated by GPUs using the MPI library and the NVIDIA CUDA API (Bard and Dorelli, 2014; Bard, 2016; Bard and Dorelli, 2018) and adapt it to simulate planetary magnetospheres. We review the underlying mathematical equations and algorithms in this section.

Following Tanaka (1994); Powell et al. (1999), we split the magnetic field vector \mathbf{B} into a background component \mathbf{B}_0 and a perturbed, evolving component \mathbf{B}_1 such that $\mathbf{B} = \mathbf{B}_1 + \mathbf{B}_0$. The embedded \mathbf{B}_0 is assumed to be static ($\partial\mathbf{B}_0/\partial t = 0$), divergence-free ($\nabla \cdot \mathbf{B}_0 = 0$), and curl-free ($\nabla \times \mathbf{B}_0 = 0$). This allows for more accurate handling of the magnetic field, especially near the planet where the dipole field is very strong. In order to preserve the divergence-free constraint on the evolved magnetic field, we solve the ‘‘Generalized Lagrangian Multiplier’’ (GLM) formulation of MHD (Dedner et al., 2002), with an additional Hall term added via Ohm’s Law.

100 The ideal MHD Ohm’s law is extended with the Hall term such that the electric field \mathbf{E} is given by

$$\mathbf{E} = -\frac{\mathbf{v} \times \mathbf{B}}{c} + \frac{\mathbf{J} \times \mathbf{B}}{nec}, \quad (1)$$

with c the speed of light, e the elementary charge, n the plasma number density, \mathbf{v} the plasma bulk velocity vector, and $\mathbf{J} = \frac{c}{4\pi} \nabla \times \mathbf{B}$ the current density vector. We note that since the background magnetic field \mathbf{B}_0 is curl-free in our formulation, the current density is taken to be the curl of the perturbation \mathbf{B}_1 .

105 We normalize the density (ρ), magnetic field, and length scale to reference values ρ_0 , B_w , and L_0 , respectively. \mathbf{v} is normalized to $v_0 = v_{A,0} = B_w/\sqrt{4\pi\rho_0}$, the pressure P to $P_0 = B_w^2/(4\pi)$, and the time t to $t_0 = L_0/v_0$. The normalized plasma beta $\beta_0 = \frac{P_0}{B_w^2/8\pi}$ can be used in place of setting P_0 directly; the conversion between the two is $\beta_0 = 2 P_0$.

This results in the set of equations:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \quad (2)$$

$$110 \quad \frac{\partial \rho \mathbf{v}}{\partial t} + \nabla \cdot \left[\rho \mathbf{v} \mathbf{v} + \left(p + \frac{B_1^2}{2} + \mathbf{B}_0 \cdot \mathbf{B}_1 \right) \mathbb{I} - \mathbf{B}_1 \mathbf{B}_1 - \mathbf{B}_0 \mathbf{B}_1 - \mathbf{B}_1 \mathbf{B}_0 \right] = 0, \quad (3)$$

$$\frac{\partial \mathcal{E}}{\partial t} + \nabla \cdot \left[\left(\frac{\rho v^2}{2} + \frac{\gamma}{\gamma-1} p \right) \mathbf{v} + B_1^2 \mathbf{v}_T + (\mathbf{B}_0 \cdot \mathbf{B}_1) \mathbf{v}_T - (\mathbf{v}_T \cdot \mathbf{B}_1) (\mathbf{B}_0 + \mathbf{B}_1) \right] = 0, \quad (4)$$

$$\frac{\partial \mathbf{B}_1}{\partial t} + \nabla \cdot [\mathbf{v}_T \mathbf{B} - \mathbf{B} \mathbf{v}_T] + \nabla \psi = 0, \quad (5)$$

$$\frac{\partial \psi}{\partial t} + c_h^2 \nabla \cdot \mathbf{B} = -\frac{c_h^2}{c_p^2} \psi, \quad (6)$$

where $\mathcal{E} = \rho v^2/2 + p/(\gamma-1) + B_1^2/2$ is the total energy density, γ is the ratio of specific heats (taken to be 5/3 in all of our simulations), and $\mathbf{v}_T = \mathbf{v} + \mathbf{v}_H$ combines the bulk velocity (\mathbf{v}) with the normalized Hall velocity $\mathbf{v}_H = -\bar{\delta}_i \mathbf{J}/\rho$. The ion inertial length $\delta_i = c\sqrt{m_i}/\sqrt{4\pi n_0 e^2}$ is normalized to the reference length such that $\bar{\delta}_i = \delta_i/L_0$. The normalized $\bar{\delta}_i$ in our simulation is a fixed parameter that can be changed at run-time. We evaluate the normalized current density ($\mathbf{J} = \nabla \times \mathbf{B}_1$) at cell centers and linearly interpolate to the cell edges when needed.

ψ is a scalar function whose evolution is designed to be equivalent to $\nabla \cdot \mathbf{B}$; c_h and c_p are parameters for the propagation and
120 dissipation of local \mathbf{B} divergence errors, respectively. Following Dedner et al. (2002), we set c_h as the global maximum wave
speed over the individual cells and set c_p such that $c_p^2/c_h = 0.36$. Although Dedner et al. (2002) recommended $c_p^2/c_h = 0.18$
and this value works very well to control the magnetic divergence in non-magnetospheric simulations, we find that some
level of tweaking is required because of the accumulation of divergence errors at the inner boundary. To ameliorate further
complications caused by this issue, we separate the momentum equation into a non-magnetic flux and a magnetic source term:

$$125 \quad \frac{\partial \rho \mathbf{v}}{\partial t} + \nabla \cdot [\rho \mathbf{v} \mathbf{v} + p \mathbb{I}] = \mathbf{J} \times (\mathbf{B}_1 + \mathbf{B}_0) , \quad (7)$$

which prevents divergence errors from inducing a non-physical acceleration along magnetic field lines (Brackbill and Barnes,
1980), but with some loss of accuracy across shock jumps.

The overall system is evolved via a time-explicit second-order Runge-Kutta scheme coupled with a simple HLL Riemann
solver (Harten et al., 1983; Toro, 1999) and a monotonized central limiter (e.g. Tóth et al. (2008)) with the slope-limiting
130 parameter β set to 1.25. For numerical stability, the explicit timestep is determined by the global Courant condition: $\Delta t =$
 $C \Delta x_{min} / v_{max}$. The Courant parameter is $C = 0.325$, $\Delta x_{min} = 0.2 R_E$ is the smallest cell length in the simulation, and
 v_{max} is the maximum wavespeed in the simulation. For Hall MHD, $v_{max,i} = |v| + |v_f| + |v_w|$ is estimated in each grid cell i
using the fast magnetosonic (v_f) and whistler wave (v_w) speeds (Huba, 2003; Tóth et al., 2008):

$$v_f = \left[0.5 \left(v_A^2 + v_s^2 + \sqrt{(v_A^2 + v_s^2)^2 - 4v_A v_s} \right) \right]^{1/2} ; \quad (8)$$

$$135 \quad v_w = \bar{\delta}_i \frac{\pi \|\mathbf{B}\|}{\rho \Delta x} , \quad (9)$$

with $v_A^2 = B^2/\rho$ the normalized Alfvén speed and $v_s^2 = \gamma P/\rho$ the normalized sound speed. The highest value of $v_{max,i}$ across
all cells is used to set the global timestep.

3 Problem Initialization

For our simulation setup, we choose normalized solar wind and terrestrial magnetic field parameters such that the magnetopause
140 standoff distance matches that of Earth’s magnetosphere ($\approx 10 R_E$), the bow shock standoff distance is $\approx 3 R_E$ beyond the
magnetopause, and that $\bar{\delta}_i$ is equivalent to the planetary radius.

These relative distances can be controlled by setting four dimensionless parameters¹:

1. $M_A = v_{sw}/v_{A,sw}$: the solar wind Alfvénic Mach number,
2. $\beta_{sw} = 8\pi P_{sw}/B_{sw}^2$: the solar wind plasma beta,
- 145 3. $\|B_0\|/\|B_{sw}\|$: the ratio of the dipole field strength at $1 R_E$ to the solar wind magnetic field,

¹In resistive MHD, there is a fifth dimensionless parameter: the Lundquist number S , which sets the resistive dissipation scale. However, we do not
explicitly define resistivity in this code; thus, we will not consider S here and instead leave this for future studies.

4. $\bar{\delta}_i$: the ion inertial length.

Since only the first three of these parameters control the magnetopause and bow shock standoff distances, we can arbitrarily set $\bar{\delta}_i$ to control the relative Hall scale. This allows our theoretical magnetosphere to be simultaneously “Earth-like” (in a relative physical sense) and “ion-scale” (relative to δ_i).

150 Thus, we choose our reference values as follows: $L_0 = R_E = 6.371 \times 10^8$ cm = 6371 km, $n_0 = 5$ cm $^{-3}$, $\rho_0 = m_i n_0$ with the mass of each ion $m_i = 6.546 \times 10^{-21}$ g = 3942.18 amu, and $B_w = 10^{-4}$ G = 10 nT. From these, we derive $v_0 = 97.5 \times 10^5$ cm/s = 97.5 km/s, $t_0 \approx 65$ s, $P_0 = 7.96 \times 10^{-10}$ Ba = 0.0796 nPa, and $\delta_i = 6371$ km = $1 L_0 = 1 R_E$.

The solar wind is initialized with values $\rho_{sw} = 1 \rho_0$, $v_{sw} = 4.09 v_0 = 400$ km/s, and wind plasma $\beta_{sw} = 0.305$ such that $P_{sw} = 0.1526 P_0$. The wind magnetic field is initially set to $\mathbf{B}_{sw} = (-0.174, 0, 0.985) B_w$ for a northward IMF with magnitude
155 $B_{sw} = 1 B_w$; we later flip the IMF by setting $B_z = -0.985$.

The planetary background magnetic field (\mathbf{B}_0) is approximated with a magnetic dipole

$$\mathbf{B}_0 = \frac{3(\mathbf{m} \cdot \mathbf{r})\mathbf{r} - m\|\mathbf{r}\|^2}{\|\mathbf{r}\|^5} \quad (10)$$

with \mathbf{r} the position vector from the center at $(0, 0, 0)$ and the planetary dipole moment $\mathbf{m} = (M_x, M_y, M_z)$ taken as $(0, 0, -3000)$, such that $\|B_0\| = 3000 B_w = 0.3$ G on the magnetic equator at $r = 1 R_E$. This satisfies the requirement that \mathbf{B}_0 be both curl-
160 free and divergence-free.

As a summary, the dimensionless parameters for this experimental magnetosphere are: $M_A = 4.09$; $\beta_{sw} = 0.305$; $\|B_0\|/\|B_{sw}\| = 3000$; $\bar{\delta}_i = 1$. For Earth, $\bar{\delta}_i \approx 1/70$ and the other parameters would be the same. For Mercury, the dimensionless parameters would be, e.g., $M_A = 6$; $\beta_{sw} = 0.65$; $\|B_0\|/\|B_{sw}\| = 15$; $\bar{\delta}_i = 1/65$.

At the inner boundary, we had difficulties with density depletion causing large local Alfvén speeds and small global
165 timesteps. We tried several types of inner boundaries, experimenting with different combinations of floating (zero-gradient) and fixing the plasma variables. Ultimately, although the following inner boundary conditions are not entirely realistic, they allow a stable evolution of the magnetosphere in both the dayside and the tail. We set the inner boundary at a radius of $3 R_E$; in these ghost cells, we fix the density at $4 \rho_0$, float the pressure, float the radial magnetic field, set the tangential \mathbf{B} to zero, and set the velocity to zero. For the divergence cleaning, we find that simply setting the ghost $\psi_c = 0$ works better than having
170 a floating condition. We note that in more realistic magnetospheres, cold plasma from the ionosphere may flow out to the tail and impact the dynamics. We will leave this topic to future studies.

For the outer boundaries, the left edge of the simulation domain fixes the conservative variables to the background solar wind condition; the rest of the box has zero-derivative boundaries for all variables.

The simulation coordinates are defined with $-X$ pointing towards the Sun, Z along the planetary magnetic dipole axis, and
175 $+Y$ ($-Y$) towards the dusk (dawn) completing the orthogonal set. Although the planet does not rotate, dawn and dusk are used assuming the sun rises in the east. In order to resolve the artificially inflated δ_i , we choose 5 cells per $\bar{\delta}_i$, giving a minimum resolution of $\Delta x, \Delta y, \Delta z = 0.2 R_E$. This resolution is set within the range $-20 R_E < x < 20 R_E$; $-15 R_E < y, z < 15 R_E$; beyond this the cell length increases by 7% with each additional cell up to a maximum of $5 R_E$ or until it hits the boundary.

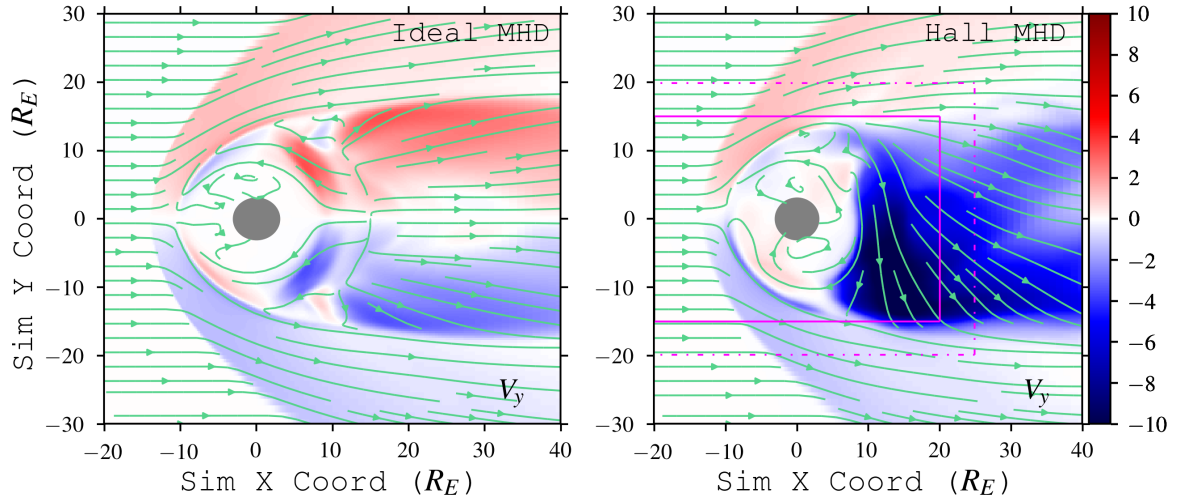

Figure 1. Cross-tail velocity V_y in the tail plane perpendicular to reconnection for both ideal (left) and Hall (right) MHD, normalized to $v_0 = 97.9$ km/s. Streamlines show in-plane velocity. Purple lines in the right figure surround the highest resolution regions: $\Delta x, \Delta y = 0.2 R_E$ (solid); $\Delta x, \Delta y \leq 0.515 R_E$ (dot-dashed). A typical Dungey-like, symmetric convection pattern induced by numerical resistivity is clearly demonstrated in ideal MHD. Adding the Hall term induces out-of-reconnection-plane flows which drives an asymmetric convection pattern; this is similar to what has been simulated for Ganymede (Dorelli et al., 2015; Tóth et al., 2016; Wang et al., 2018).

The total size of the grid is $290 \times 253 \times 253$ (just over 18 million cells), covering a domain of $-35.6R_E < X < 122R_E$,
 180 $-86.4R_E < Y, Z < 86.4R_E$.

We start the simulation in ideal MHD ($\bar{\delta}_i = 0$) with a northward IMF (\mathbf{B}_{sw} given above) for $120 t_0$, and then flip $B_{z,sw}$
 for the southward IMF case and run it for another $120 t_0$. At this point, we turn on the Hall term by setting $\bar{\delta}_i = 1$ and run it
 for another $12 t_0$ in order to allow the perturbations induced from the abrupt change of physics to settle. From this point on,
 the simulation was run for $45 t_0$ under continuous pure southward IMF and with the Hall term on. The main results discussed
 185 below come from this final portion of the run with the Hall term enabled.

4 Results and Discussion

4.1 Hall-induced asymmetry

Prior to turning on the Hall term, the magnetospheric convection is of Dungey-type. Turning the Hall term on, however, induces
 an out-of-reconnection-plane $\mathbf{E} \times \mathbf{B}$ force which breaks that symmetry, and drives convection in a preferred direction (Figure
 190 1). This convection also modifies the current sheet structure between ideal and Hall MHD (Figure 2), and causes it to vary in
 length along the x -direction across the tail y -coordinate. For smaller magnetospheres, this effect was first seen in non-ideal
 MHD simulations of Ganymede (Dorelli et al., 2015; Tóth et al., 2016; Wang et al., 2018); this was later seen in 10-moment

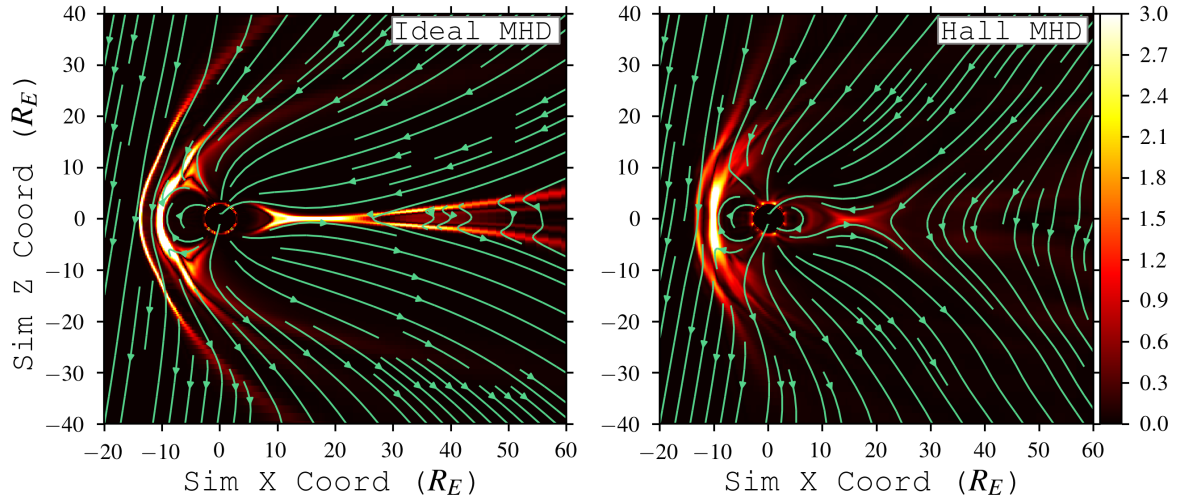

Figure 2. Normalized Current Density Magnitude $\|J\|$ in the simulation xz -plane at $y = 0$ for both ideal (left) and Hall (right) MHD. Streamlines show in-plane magnetic field. Adding the Hall term induces out-of-reconnection-plane flows (Fig. 1); the resulting tail convection causes the magnetotail current sheet to vary along the x -direction across the tail width (y) (see, e.g., Figs. 7 and 9 for examples of $\|J\|$ spatial variation in the xy -plane).

and embedded-kinetic simulations of Mercury (Dong et al., 2019; Chen et al., 2019). Our simulation supports the idea that this Hall-induced drift is sufficient to produce an asymmetry: kinetic effects are not required, but they may manifest different kinds of asymmetry.

Finally, since our choice of $\min \Delta x, \Delta y, \Delta z = 0.2 R_E$ is based on the normalized $\delta_i = 1 R_E$, we check here that we are able to correctly resolve δ_i in the tail. As Figure 3 illustrates, the local values of δ_i exceed $1 R_E$ in the magnetotail, and may reach up to $5 R_E$. Thus, we are appropriately resolving the Hall length scales in the tail.

4.2 Dipolarizations

In our simulation, the Hall electric field induced by tail reconnection accelerates ions towards the duskside and the electrons towards dawn. Since $\delta_i = R_E$ here, the reconnection current sheet spans a significant fraction across the tail; this means that the ions are decoupled from the magnetic field during much of their in-plane convection duskward (green arrows in Figure 4). The electrons, being coupled to the magnetic field, carry the reconnected, normal B_z flux downward (blue arrows). Because the reconnected magnetic flux originates over a large region within the tail, there is a significant pileup leading to a reconnecting, active region of plasmoid formation on the dawnside. This pileup + reconnection mechanism may be a general cause of dipolarizations in ion-scale magnetospheres (like Mercury, e.g. Sundberg et al. (2012)). Although the drifting electrons themselves do not cause dipolarization events, they can affect where events occur. We speculate that increasing the system size relative to δ_i will limit the extent of downward flux transport via current sheet electrons and cause the flux pileup to shift closer

Figure 3. Density (left) and local value of δ_i (right) calculated via $\delta_{i,\text{local}} = \sqrt{1/\rho}$ in the xy - (top) and xz -planes (bottom), taken from an example snapshot during the final Hall MHD portion of the run. Density is normalized via $n_0 = 5\text{cm}^{-3}$ and $m_i = 3942$ amu; δ_i is normalized via $L_0 = R_E$. Purple lines denote same regions as Figure 1: solid lines denote region with $\Delta x, \Delta y, \Delta z = 0.2 R_E$; dashed lines denote $\Delta x, \Delta y, \Delta z \leq 0.515 R_E$. Most of the near-tail region (within purple boxes; $x > 0$) has > 5 cells/local δ_i

Figure 4. Cross-tail convection in the reconnection plane at $z = 0$, with background color (orange) illustrating normalized current sheet density magnitude. Blue (green) streamlines indicate direction of electron (ion) velocity (normalized via $v_0 = 97.9\text{km/s}$), with line sizes proportional to the magnitude of the maximum electron (ion) velocity in the plane. The electron velocity (in normalized units) is calculated from $\mathbf{v}_e = \mathbf{v} - \mathbf{J}/\rho$.

to tail center (or duskward). In other words, this type of asymmetry we observe here may be more pronounced in δ_i -scale
 210 magnetospheres and weaker in larger magnetospheres. However, it is unknown how this mechanism will interact with the
 overall Hall-induced duskward ion convection, which will begin to dominate electron convection at scales $\gg \delta_i$.

During the $45 t_0 \approx 48$ minute duration of our simulation there were 7 events visually observed on the dawnside (none on
 the duskside) which followed the general substorm pattern of a buildup/loading phase followed by a unloading (or expan-
 sion/relaxation) phase (Rostoker et al., 1980). For each event, we observed pileup of the normal B_z magnetic flux over a period
 215 of several minutes, followed by a burst of reconnection and the subsequent ejection of plasmoids tailward (Figs. 5 and 6).
 Three of the seven events produced large plasmoids (on the order of $10R_E = 10\delta_i$), while the rest resulted in smaller ones
 ($\leq 5R_E; \leq 5\delta_i$). The larger ejecta appeared to build up and release on timescales around 10 minutes, while the smaller events
 had shorter time scales around 5 minutes. Most events originated at a down-tail distance $\approx 13 - 16 R_E$; after ejection, their
 resulting plasmoids traveled to about $30R_E$ down-tail over several minutes before dissipating.

220 The observed dawnward bias in dipolarization events for our ion-scale magnetosphere corroborates similar dawnward biases
 found in MESSENGER observations (Sun et al., 2016; Dewey et al., 2018) and global simulations of Mercury (Dong et al.,
 2019; Chen et al., 2019). It is interesting to note that our results are under a steady, southward solar wind condition. As long
 as there is Hall-driven convection in the tail, the competition between dawnside B_z pileup and reconnection drives this cycle.
 At the moment, it is not clear whether this process is unique to our ion-scale Earth, since its strong planetary dipole field
 225 means that flux piles up over a large swath of the tail. It is possible that a similar process may occur at Mercury (which has
 a weaker dipole field), i.e. that its observed dipolarizations are indeed akin to global substorms (Kepko et al., 2015). Further

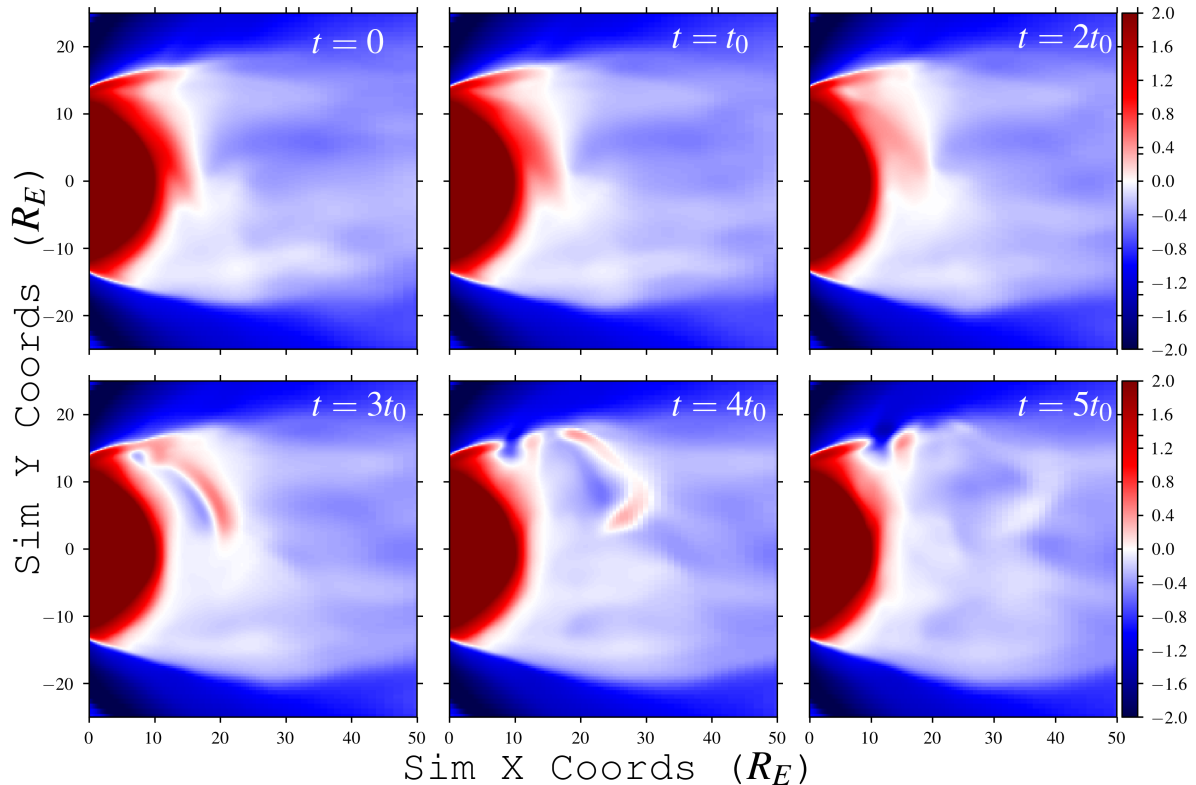

Figure 5. Formation and evolution of a global dipolarization over $5 t_0 \approx 5.4$ minutes, as seen in the evolution of magnetotail normal magnetic field B_z (red: out-of-page; blue: into page). Displayed times are relative to upper left image; $t = 0$ here corresponds to $6t_0$ after the start of the $45t_0$ Hall MHD simulation period. B_z has been normalized via $B_w = 10^{-4}$ G.

investigation is needed to determine how varying the magnetospheric parameters (as presented in Section 3) affects these observations, especially as system size increases relative to δ_i .

We note that, at Earth, there are additional localized (not global) dipolarization fronts resulting from current sheet instabilities or transient reconnection events (e.g. Runov et al. (2009); Sitnov et al. (2009)). We do not see these small-scale fronts in our ion-scale Earth; this may be because we do not have enough down-tail resolution to observe localized current sheet instabilities which form them.

4.3 Current Sheet Thickness

Another test of the “active region” picture is the predicted thickness asymmetry of the tail current sheet: Liu+ predicted that the sheet would be thinner on the dawnside. We follow Poh et al. (2017a) and estimate the current sheet thickness in our model

Figure 6. Formation and evolution of a global dipolarization due to locally reconnecting magnetic field lines in the xy and xz planes, as seen in the evolution of magnetotail current density ($\|J\|$) and normal magnetic field B_z . $\|J\|$ is normalized via $J_0 = B_w/L_0$; B_z is normalized via $B_w = 10^{-4}$ G. Displayed times are relative to the sequence shown in Fig. 5. The cyan dashed line in the left figures mark the y -position of the xz cuts in the center and right figures.

by using a Harris sheet (Harris, 1962):

$$B_x = B_a \tanh \frac{Z - Z_0}{L_{CS}} + \text{offset}, \quad (11)$$

where B_a is the asymptotic lobe field, Z_0 is the current sheet center, L_{CS} is the current sheet half-thickness, and the offset allows for asymmetry between the north and south B_x lobes on either side of the current sheet. We take 6000 one-dimensional cuts of B_x along the north-south direction between $z = \pm 10 R_E$ in a volume covering the current sheet from $12 R_E < x < 16 R_E$ and $-15 R_E < y < 15 R_E$, randomly sampled across the box plane and during the final $45 t_0 \approx 48$ minute period (example shown in Fig 7). These cuts are fit to eq. 11 using the Levenberg-Marquadt least-squares algorithm in `scipy.curvefit` (Virtanen et al., 2020); instances that do not fit well ($\chi^2 > 0.01$) or that return nonsensical results ($L_{CS} < 0$) are rejected. This results in 5037 samples of the current sheet thickness across the magnetotail (Figure 8). This distribution shows that the

Figure 7. Example of B_x sampling and Harris sheet fit (right figure) as described in text (eq. 11). $\chi^2 = 0.004$ for this fit. B_x has been normalized via $B_w = 10^{-4}$ G = 10 nT. The left figure shows the magnetotail current sheet magnitude (normalized via $J_0 = B_w/L_0$) in the simulation $z = 0$ plane; the B_x sampling box domain boundaries are shown in cyan, with the small cross showing the location of the example sample. The box boundaries are $12 < x < 16$ and $-15 < y < 15$.

245 dawnward current sheet is thinner on average than the duskward sheet. However, there is a significant scatter in this result; the dawn sheet covers a wider range of thicknesses. This variation is caused by the dawnside pileup+reconnection mechanism.

The current sheet oscillates with the dipolarization cycle (Sec. 4.2) between a "thick state" due to the B_z pileup and a "thin state" immediately following the flux unloading and plasmoid ejection. This is demonstrated in Fig. 9, where fitted CS thicknesses during both flux loading and unloading stages are plotted along with snapshots of the B_z state. During the loading
 250 stage, the piled-up flux on the dawnside ($5R_E < y < 12R_E$) fattens the current sheet; here, the sampled dawn thicknesses are comparable to and can exceed the dusk thicknesses. However, after the unloading stage, the current sheet on the dawnside is much thinner where the flux has been evacuated (bottom right plot; $R > 15R_E$). Interestingly, we can see that where the B_z flux remains ($R < 15R_E$), the current sheet continues to be thick. Combining all the sample fits over several cycles of loading and unloading results in the picture shown in Fig. 8: a dawnward current sheet moving between thick and thin states depending
 255 on the level of flux pileup. Indeed, this is a common pattern throughout the simulation: where there is flux pileup, the current sheet is thicker and the current density is lower (e.g. Fig. 10).

This cycle may explain the apparent contradiction between the Liu+ prediction of thinner dawnward current sheets in ion-scale magnetospheres and the Poh et al. (2017b) spacecraft observation of thicker dawnward sheets at Mercury. Even though, on average, the current sheet is thinner dawnward (as Liu+ predicts), the sampling of measurements could be producing the
 260 opposite result. As shown in Figs. 8 and 9, the sampled sheet thickness can greatly depend on where and when the craft

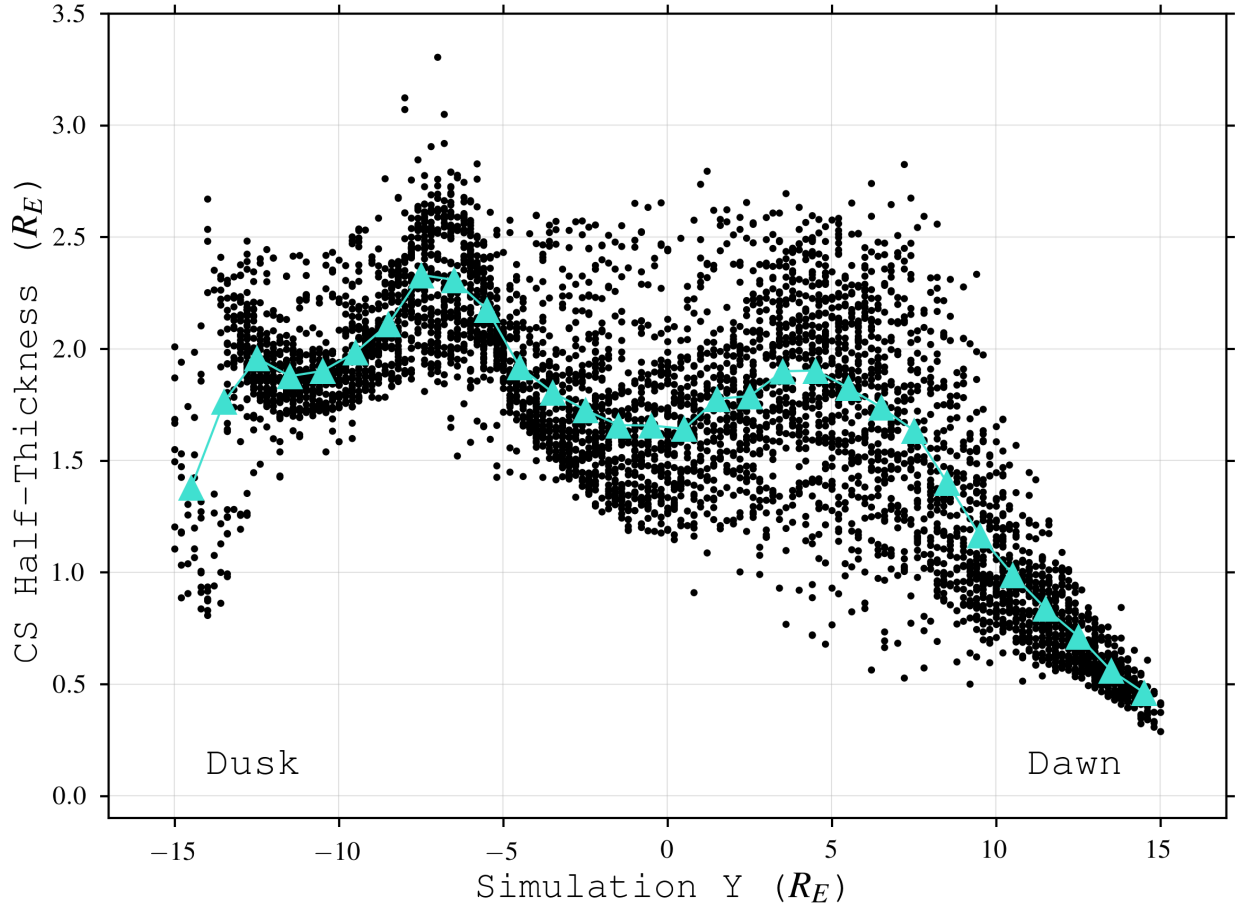

Figure 8. Best-fit current sheet half-thicknesses (L_{CS} derived by fitting eq. 11 to 5037 cuts of B_x along the z -direction. These cuts were randomly sampled in the tail xy -plane and over the simulation time period (see text). There is a bias towards the current sheet being thinner on the dawnside. However, the dawnside also sees a larger spread in thicknesses: this is a result of temporal effects (see main text for discussion).

Figure 9. Cross-comparison of current sheet density magnitude (left), current sheet B_z flux pileup (center; same parameters as Fig. 5) and sampled thicknesses (right) during (top row) and after (bottom row) a global dipolarization event. Current sheet fits are sampled from the area within the wedges ($13R_E < R < 17R_E$). The current sheet is thick where the B_z flux has piled up, and thin where the flux has been unloaded. There is a $2.25 t_0 \approx 2.4$ minute time difference between the snapshots of the top and bottom rows.

crosses the tail. In our simulation, the current sheet is continuously morphing between “thick” and “thin” states; both types of regions exist simultaneously within the dawnside. Most points in the tail preferentially see thicker sheets over time, though some preferentially see thinner sheets. It is possible that these effects combine to produce a sampling bias in time and space towards thicker sheets. We note that this is speculation, and will require more investigation with respect to the various solar wind driving conditions and seasons that MESSENGER experiences at Mercury.

5 Conclusion

We have simulated a small, “ion-scale Earth” in which the standoff distance and magnetotail width are akin to Earth’s as measured in planetary radii, but with the solar wind ion-scale length δ_i set to $1 R_E$. The resulting tail plasma behavior was more similar to Mercury’s magnetosphere than Earth’s. Along with Chen et al. (2019); Dong et al. (2019), our results support the idea that tail asymmetry is a universal consequence of the Hall effect in ion-scale magnetospheres. Essentially, it is the

relative size of the magnetosphere compared to δ_i , not the absolute size (planetary radii), that controls the importance and influence of Hall-induced consequences. We find that Hall effects are sufficient to generate tail asymmetries in dipolarization, plasmoids, and current sheet thickness. No electron-scale kinetic effects are required, though they may contribute to or modify asymmetries. However, we emphasize that we did not simulate the same magnetosphere as Chen et al. (2019): our “ion-scale Earth” is smaller relative to δ_i than Mercury and has different magnetospheric parameters (Section 3). There may be additional effects not being considered, especially with regards to how varying the dimensionless magnetospheric parameters affect the manifestation of tail asymmetries.

In general, our simulation appears to corroborate the Liu+ picture of tail asymmetry in ion-scale magnetospheres; however, the Lu+ finding that the transported tail B_z thickens the current sheet is readily manifested here. Although the reconnected B_z does drive outflows and thin current sheets on the dawnside, we see that it can pile up and thicken current sheets. There is a continuous cycle between the dawnward transport of B_z leading to pileup (which thickens the current sheet) and reconnection (which thins the current sheet); this manifests in an oscillating current sheet thickness. On average, we find the current sheet is thinner on the dawnside, but it can occasionally be thicker in some regions depending on the level of flux pileup.

Further study will be required to confirm or contrast this picture for magnetospheres with system size $\gg \delta_i$. Since our simulation is of a experimental magnetosphere, several questions concerning more realistic magnetotails remain:

- How does the weaker, offset dipole of Mercury affect the amount of magnetic flux available for transport/pileup and the resulting plasmoid formation/ejection?
- Are the observed dipolarizations at Mercury actually “global”, like substorms?
- How does increasing the system size / δ_i ratio affect asymmetry formation, tail convection, transport of B_z , and plasmoid/DF formation?
- What other effects (e.g. kinetic, ionosphere) cause asymmetries and how do they interact with the Hall effect and one another?

We look forward to future studies which will investigate these questions in greater detail.

Code availability. Observational data were not used, nor created for this research; the model algorithm is described above and in the references; simulation parameters are given for reproducing the magnetosphere.

Author contributions. C.B. developed the code, analyzed the simulation results, wrote the manuscript and produced the figures. J.D. edited the manuscript and provided computing resources. Both authors conceptualized the research goals and guided the direction of inquiry.

Competing interests. The authors declare that they have no conflict of interest.

Figure 10. 1D cuts of tail magnetic field B_z (top) and current density magnitude $\|J\|$ (bottom) taken from $x = 15 R_E$, $-15 R_E < y < 15 R_E$ in the $z = 0$ equatorial plane. $\|J\|$ is normalized via $J_0 = B_w/L_0$; B_z is normalized via $B_w = 10^{-4}$ G. Colors denote times relative to $t = 0$ in Figure 5 (top left box). Arrows highlight where local pileup of B_z on dawnside thickens the current sheet, resulting in a lower current density and impeding local reconnection.

Acknowledgements. The authors acknowledge funding from NASA's Heliophysics Internal Scientist Funding Model (HISFM) program.

300 C.B.'s software development was partly supported by an appointment to the NASA Postdoctoral Program at NASA-Goddard Space Flight Center, administered by Universities Space Research Association under contract with NASA. C.B. thanks Alex Gloer for useful discussions concerning simulation techniques. C.B. thanks Ryan Dewey for helpful discussions concerning Mercury tail asymmetries/MESSENGER observations. Plots were created using matplotlib (Hunter, 2007). The authors thank Gabor Toth and the unnamed referee for very helpful comments which improved this manuscript. Observational data were not used, nor created for this research; the model algorithm and

305 simulation parameters are described above.
