## 10 **Abstract**

11

12 This study examines the relationship between the concentration of atmospheric sodium and its  
13 Meteoric Input Function (MIF). We use the measurements from the Colorado State University (CSU)  
14 Lidar and the Andes Lidar Observatory (ALO) with a new numerical model that includes sodium  
15 chemistry in the mesosphere and lower thermosphere (MLT) region. The model is based on the  
16 continuity equation to treat all sodium-bearing species and runs at a high temporal resolution. The  
17 model simulation employs data assimilation to compare the MIF inferred from the meteor radiant  
18 distribution and the MIF derived from the new sodium chemistry model. The simulation captures the  
19 seasonal variability of sodium number density compared with lidar observations over the CSU site.  
20 However, there were discrepancies for the ALO site, which is close to the South Atlantic Anomaly (SAA)  
21 region, indicating it is challenging for the model to capture the observed sodium over ALO. The CSU site  
22 had significantly more lidar observations (27,930 hours) than the ALO sites (1872 hours). The simulation  
23 revealed that the uptake of the sodium species on meteoric smoke particles was a critical factor in  
24 determining the sodium concentration in MLT, with the sodium removal rate by uptake found to be  
25 approximately three times that of the NaHCO<sub>3</sub> dimerization. Overall, the study's findings provide  
26 valuable information on the correlation between MIF and sodium concentration in the MLT region,  
27 contributing to a better understanding of the complex dynamics in this region. This knowledge can  
28 inform future research and guide the development of more accurate models to enhance our  
29 comprehension of the MLT region's behavior.

30

31 **Keywords:** Sodium layer, sodium chemistry, Meteor radiant distribution, Meteoroid input function

32

## 33 **Key points:**

- 34 ● A high-time resolution, time-dependent Na chemistry model is developed.
- 35 ● Ablated global meteoroid material inputs inferred from ALO and CSU observations are about 83  
36 t d<sup>-1</sup> and 53 t d<sup>-1</sup>, respectively.
- 37 ● The frequency of meteor occurrences might not provide a precise reflection of the mass of  
38 meteoroid material input.

39

40

## 41 1. Introduction

42 Micro-meteoroids enter the Earth's atmosphere day and night, depositing their constituents into the  
43 atmosphere via ablation, creating a region that hosts various metal species, for example, Fe, K, Si, Mg,  
44 Ca, and Na, in both neutral and ion form (Plane et al., 2015; Plane et al., 2021; and references therein).  
45 The region is commonly referred to as the mesosphere and lower thermosphere (MLT), located between  
46 75 and 110 km altitude. The metal layers in the MLT often serve as the tracers that facilitate the  
47 investigation of the dynamical and chemical processes within the region (Takahashi et al., 2014; Qiu et  
48 al., 2021). Quantitative measurements of metal atoms have been made since the 1950s (Hunten, 1967)  
49 through a variety of ground or space-borne technologies (Koch et al., 2021; Koch et al., 2022). The large  
50 resonant scattering cross-section (Bowman et al., 1969) and the substantial presence of the sodium  
51 atom in the MLT make it one of the most researched metal layers in the atmosphere (Yu et al., 2022).

52 The sodium layer is usually studied via observations carried out by resonance lidars, satellites, and  
53 through Na D-line emission at 589.0nm and 589.6nm (Plane, 2010; Plane et al., 2012; Hedin and  
54 Gumbel, 2011; Langowski et al., 2017; Andrioli et al., 2019; Li et al., 2020a). The sodium vertical profiles  
55 retrieved by lidars have been commonly used as a tracer to study atmospheric dynamics, e.g., gravity  
56 waves, wind shear, etc. The long-term seasonal and short-term diurnal variability of metallic species  
57 have been investigated by several studies (Feng et al., 2013; Marsh et al., 2013; Cai et al., 2019a, b; Yu et  
58 al., 2022). A typical sodium chemistry scheme consists of neutral chemistry, ion chemistry, and  
59 photolysis. The sodium chemistry research in recent years has primarily been based on the sodium  
60 chemistry model by Plane (2004), which has been cited in various subsequent works, including Bag et al.  
61 (2015) and references therein.

62 As meteoroids are the primary source of metal layers in the atmosphere, including the sodium layer,  
63 the Meteoroid Input Function (MIF) plays a crucial role in the modeling of metallic layers in the  
64 atmosphere. The MIF is a function designed to model the impact of the temporal and spatial variability  
65 of the meteoroid on the atmosphere (Pifko et al., 2013). Sporadic meteors are estimated to make up  
66 more than 95% of the total meteoroid population by comparing the number of meteors originating in  
67 sporadic sources to those originating in known shower meteor sources (Chau and Galindo, 2008). This  
68 highlights the importance of incorporating sporadic meteor data in the MIF to accurately understand  
69 sodium concentration in the mesosphere and lower thermosphere (MLT) region and its correlation with  
70 meteoroid material input. It is well established that there are six apparent sources of sporadic meteors,  
71 namely North and South Apex (NA and SA); North and South Toroidal (NT and ST); and Helion and Anti-  
72 Helion sources (H and AH) (Campbell-Brown, 2008; Kero et al., 2012; Li et al., 2022). However, the  
73 relative strength of these meteor radiant sources varies among the studies. For example, the NA and SA  
74 sources are found to be much stronger than other sources in results obtained with High Power Large  
75 Aperture (HPLA) radars (Chau et al., 2007; Kero et al., 2012; Li and Zhou, 2019), while specular meteor  
76 radars found the difference to be much smaller (Campbell-Brown and Jones, 2005; Campbell-Brown,  
77 2008). The detection sensitivity varies significantly among different facilities. For instance, the Arecibo  
78 Observatory (AO) at 18° N, 66° W detects approximately 20 times more meteors per unit area per unit  
79 time than the Jicamarca Radio Observatory (JRO) at 12° S, 77° W, and at least 800 times more meteors  
80 than the Resolute Bay Incoherent Scatter North (RISR-N) radar at 75° N, 95° W, despite all being HPLA  
81 facilities (Li et al., 2020, 2023a; Hedges et al., 2022). While meteor flux does exhibit variations based on  
82 time and latitude, these fluctuations alone cannot explain the magnitude of the observed difference.

83 Consequently, the total mass of the meteors that enter the Earth's atmosphere is subject to significant  
84 uncertainties. In the existing Whole Atmosphere Community Climate Model-Na (WACCM-Na) global  
85 sodium model (Dunker et al., 2015), the meteor input function was modeled by placing a flux curve on  
86 each radiant meteor source with a definite ratio (more details can be found in Marsh et al., 2013). The  
87 flux curve model is based on observations carried out exclusively by the Arecibo Observatory. Although  
88 the model can reproduce some of the flux characteristics of the meteors observed at Arecibo, it is a  
89 relatively simple model and therefore has several limitations (Li et al., 2022). One of the limitations is  
90 that the model cannot reproduce the velocity distribution of the meteors in observations.

91 This study introduces a new numerical model for sodium chemistry that utilizes the continuity equations  
92 for all Na-related reactions without steady-state approximations. The main objective is to investigate the  
93 relationship between the apparent sodium concentration and the Meteoroid Input Function (MIF) in the  
94 MLT region. We then compare the results of the new model with measurements from two lidar  
95 instruments, namely the Colorado State University (CSU) and the Andes Lidar Observatory (ALO).  
96 Furthermore, we compared the MIF derived from the new sodium chemistry model and lidar  
97 measurements from CSU and ALO, against the results of the high-resolution meteor radiant distribution  
98 recently deduced from observations conducted at AO. Finally, we discuss the implications of these  
99 comparisons and suggest possible explanations for the observed discrepancy between the MIF derived  
100 from radar and those obtained from lidar observations.

## 102 **2. The sodium chemistry model (NaChem)**

### 103 **2.1 Sodium chemistry**

104 Numerical airglow models have been extensively used to investigate atmospheric airglow chemistry and  
105 gravity waves (Huang and Hickey, 2008; Huang and Richard, 2014; Huang, 2015). A new numerical  
106 sodium chemistry model, hereafter referred to as NaChem, was developed for this study. Table 1 lists  
107 the complete reactions and their corresponding rate coefficients used in NaChem, which includes  
108 neutral chemistry, ion chemistry, and photochemistry. The dimerization reaction of  $\text{NaHCO}_3$  (reaction 25  
109 in Table 1) is the outlet that removes Na atoms in the chemistry scheme. The Na atoms can also be  
110 removed by the uptake of sodium species onto meteoric smoke particles (Hunten et al., 1980;  
111 Kalashnikova et al., 2000; Plane, 2004), a process that can be turned on or off in the model. This study  
112 estimates the MIF in the numerical model by matching the amount of sodium atoms removed by the  
113 dimerization reaction and uptake, i.e., sodium sink, to maintain the observed sodium presence in the  
114 MLT. Throughout the rest of the paper, the MIF estimated from the sodium chemistry numerical model  
115 will be referred to as MIF(s). On the other hand, the MIF derived from meteor radiant distribution will  
116 be referred to as MIF(m). MIF is a function of time and latitude, representing the mass of meteoroid  
117 material entering Earth's atmosphere. The MIF(m) is determined through a 3-D meteoroid orbital  
118 simulation, a process similar to the seeding process discussed in section 3.1 of Li et al. (2022), based on  
119 the meteor radiant distribution. MIF(m) is a relative unitless quantity. Note that the meteor mass cannot  
120 be accurately determined via radar measurements, however, the seasonal variation of meteoroid  
121 material input can be represented by MIF(m). The estimation of meteor mass is further discussed in  
122 Section 5. In contrast, MIF(s) is expressed in units of  $1/\text{cm}^3/\text{second}$ .

123 The numerical model utilizes the continuity equation to track the time evolution of all 14 Na-related  
124 species. Table 2 presents a comprehensive list of these species, along with their corresponding  
125 production and loss rates. The background major gas species, including O<sub>3</sub>, O<sub>2</sub>, O, H, H<sub>2</sub>, H<sub>2</sub>O, etc., and  
126 the temperature are provided by WACCM version 6 (Jiao et al., 2022). Here we use the dynamic version  
127 of WACCM nudged with NASA's Modern Era Retrospective Analysis for Research and Application  
128 MERRA2 reanalysis data set (Hunziker & Wendt, 1974; Molod et al., 2015; Gettelman et al., 2019). The  
129 WACCM reference profiles are linearly interpolated to a resolution of one minute and updated every  
130 minute during the simulation. It is worth noting that the Na-related reactions, which are illustrated in  
131 Table 2, do not significantly impact the background gas species, as the effect is orders of magnitude  
132 smaller than the variation of the major gas species themselves. Therefore, the major gas species are  
133 simulated independently of Na-related reactions.

## 134 2.2 Numerical scheme

135 As discussed earlier, it is worth noting that the reactions of sodium chemistry in NaChem share  
136 similarities with those in previous models (e.g., Plane et al., 2015 and references therein); however, the  
137 implementation of the numerical chemistry scheme differs. NaChem uses continuity equations to treat  
138 all chemicals involved, including short-lived intermediate species. Treating all species with the continuity  
139 equation is a more straightforward yet accurate approach than using steady-state approximations.  
140 Moreover, by treating all species in a uniform procedure, the numerical model is more compact and  
141 easier to interpret. The computational capability of a personal computer nowadays has advanced  
142 enough to process an ultra-fine time step (microseconds) that is necessary for numerical simulations of  
143 short-lived species in a reasonable duration. Still, the differential equations for production and loss of  
144 short-lived species can be numerically unstable unless microsecond or even sub-microsecond time step  
145 is used (Higham, 2002). The concern of the differential equation instability can be largely mitigated by a  
146 first-order exponential integrator (Hochbruck and Ostermann, 2010), i.e.,

$$147 \quad c = x_0 - \frac{a_0}{b_0}$$
$$148 \quad x_1 = \frac{a_0}{b_0} + ce^{-b_0\Delta t} \quad (1)$$

149 Where  $x_0$  is the value of the current step. In the simulation, it is the number density of the species.  $a_0$  is  
150 the production of the species,  $b_0$  is the loss of the species,  $\Delta t$  is the step size in time, and  $x_1$  is the value  
151 of the next step.

152 The exponential integrator, as expressed in Equation (1), is the solution to the continuity equation.  
153 Notably, reaction 25 listed in Table 1 is an exception, which was carried out using explicit Euler  
154 integrator in the simulation. This reaction's continuity equation is structured differently from the others  
155 because it represents the only mechanism for removing Na atoms from the chemistry simulation, apart  
156 from the uptakes of sodium species. Our testing indicates that both the exponential integrator and  
157 explicit Euler integrator yield nearly identical results. However, for numerical stability, the explicit Euler  
158 integrator requires a step size of  $\sim 1\mu\text{s}$ , which is orders of magnitude smaller than the exponential  
159 integrator. The default time step of NaChem is 0.1 seconds with the exponential integrator.

170

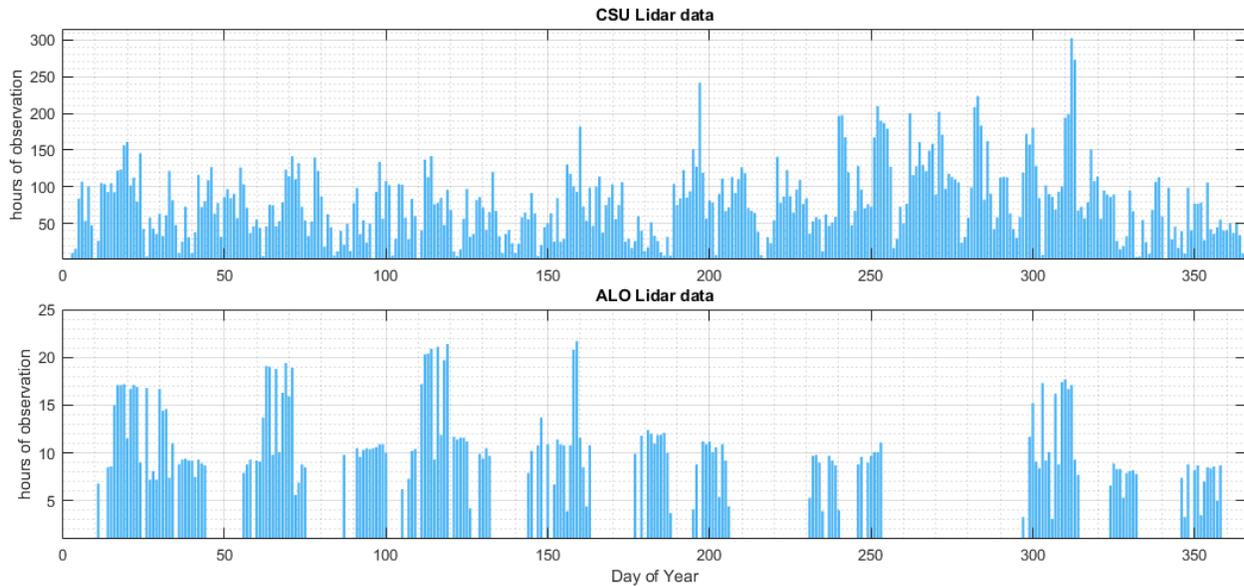

171 \*In Species 1, as of the current state of the model, all Na(2p) atoms return to their ground state  
172 immediately, so the loss term is set to 1. The [hν] is the term that represents loss via photoionization,  
173 which is approximately a sinusoidal function based on the solar zenith angle of the respective local solar  
174 time.

175

### 176 3. CSU and ALO Sodium Lidar Observations and data processing

#### 177 3.1 Observations

178 Several aspects of the current research, i.e., the presence of sodium in the MLT, require cross-validation  
179 with the measurements. One primary objective of the present model is to match the observed seasonal  
180 variation of the sodium layer. Measurements by the Colorado State University (CSU, 41.4°N, 111.5°W)  
181 Lidar, also known as Utah State University (USU) Lidar, and the lidar data acquired by the Andes Lidar  
182 Observatory (ALO, 30.3°S, 70.7°W), are used to facilitate the research in the current study. We are  
183 unable to acquire more ALO data after 2019 as the COVID situation disrupted the site operation. The  
184 CSU data comprises 27,930 hours of lidar observations between 1990 and 2020, whereas the ALO data  
185 consists of 1872 hours between 2014 and 2019.

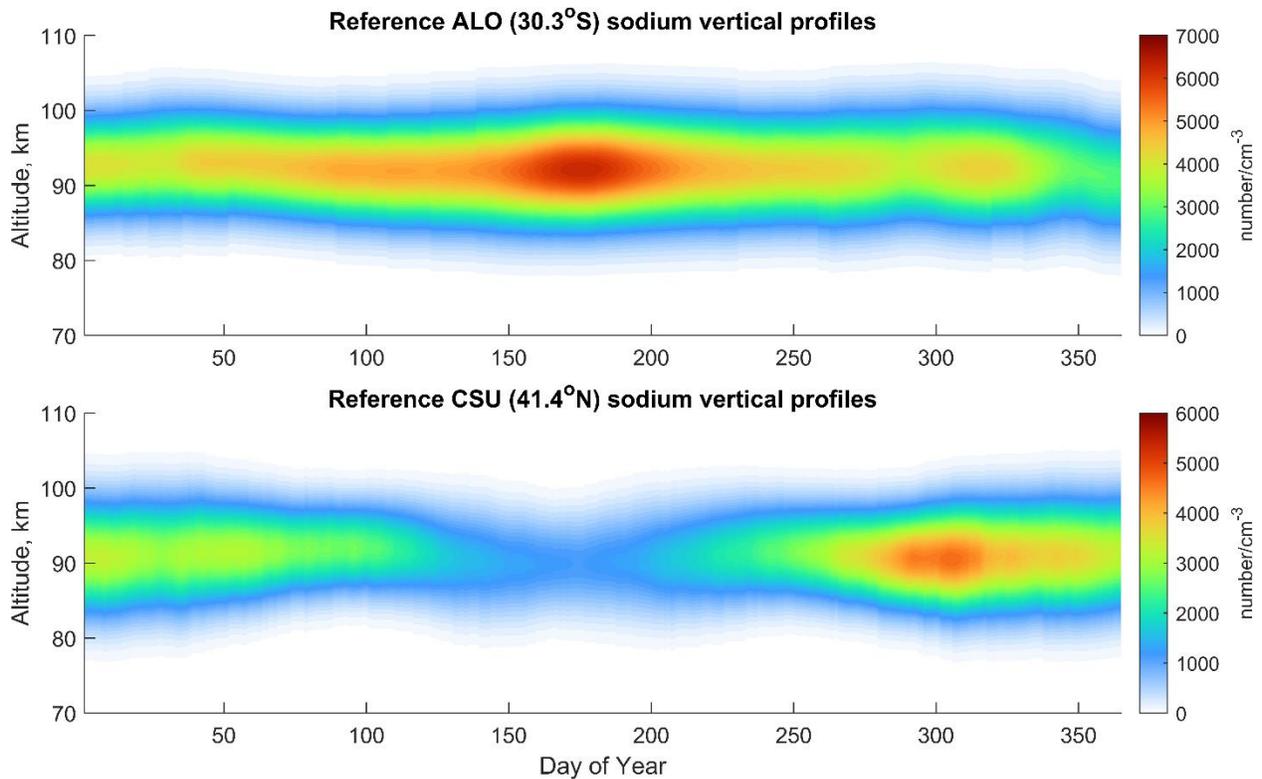

186

187 **Figure 1.** CSU lidar data from 1990 to 2020 (top plot) and ALO lidar data from 2014 to 2019 (bottom  
 188 plot).

189 The statistics of CSU and ALO available data are presented in Figure 1. The Lidar observations of both  
 190 sites consist of nocturnal observations only, and a typical nocturnal observation lasts between 8 and 11  
 191 hours. Note that in Figure 1, there could be as many as 300 hours of sodium observations on a single day  
 192 of year, which means the data of the date comprise observations of many years on that day in different  
 193 years. The CSU data almost covered every day of the year with only a few exceptions, whereas the ALO  
 194 data was much more sparse. As a result, due to the significantly larger number of CSU observations, the  
 195 statistical reliability of the seasonal variation in the sodium layer derived from ALO observations may not  
 196 be as strong as that of the CSU data. As depicted in Figure 2, the overall seasonal trend of the sodium  
 197 vertical profile derived from CSU lidar observations closely aligns with the simulation-based estimate by  
 198 Marsh et al. (2013). In contrast, ALO lidar observations deviate from the findings reported by Marsh et  
 199 al. (2013). The ALO measurements exhibit a prominent peak around June, while the results in Marsh et  
 200 al. (2013) show a double peak in March and October.

201 **3.2 Data processing**

202 The sodium layer in atmospheric observations is often affected by perturbations of atmospheric  
 203 dynamics, which is why sodium is commonly used as a tracer in the study of the MLT dynamics (Plane et  
 204 al., 2015). However, studying the sodium layer itself can be complicated due to the underlying chemical  
 205 processes coupled with the dynamics. In order to mitigate the effects of atmospheric dynamics, we  
 206 process the sodium vertical profiles from observations in three steps. First, we average the profiles by  
 207 day of the year, meaning we take the average of the data from the same day of the year from different  
 208 years. Missing data are treated using linear interpolation. Next, we smooth the averaged profiles using a  
 209 15-day running average. Finally, we further smooth the profiles by fitting them with a skew-normal  
 210 distribution (Azzalini & Valle, 1996) using the least squares error method.

211

212 **Figure 2.** *The reference annual sodium vertical profiles at ALO (top plot) and at CSU (bottom plot). The*  
 213 *reference profiles are the averages throughout all the available data on the same days at the respective*  
 214 *site, then fitted by a skew-normal distribution that mitigates atmospheric dynamics. In essence, the*  
 215 *reference profiles are measurements with small-scale dynamics removed via steps discussed in section*  
 216 *3.2.*

217

218 Figure 2 displays the processed annual sodium vertical profiles from the lidar measurements, referred to  
 219 as reference profiles hereafter. These profiles serve as references to guide the numerical simulation of  
 220 the NaChem model. The reference profiles are Na lidar measurements fitted using a skew-normal  
 221 distribution, smoothed by a 15-day running average, and processed through linear 2-D interpolation  
 222 across time and altitude. The lidar measurements have an altitude resolution of 500m for ALO and from  
 223 75m to 140m for CSU. These measurements are interpolated to a 100m resolution as inputs to the  
 224 NaChem model. The time resolutions of the lidar measurements typically vary between 1 and 10  
 225 minutes, depending on the experiment, and are linearly interpolated to 0.1 seconds. The reference  
 226 profiles inherently include diffusion and other dynamic effects on the sodium species in the MLT, as  
 227 these observational data represent snapshots of sodium diffusion at various times. By constantly  
 228 matching the observed Na profile to the simulated Na profile, the diffusion is included implicitly in the  
 229 model. The seasonal column densities of both ALO and CSU profiles are similar to a sinusoidal function,  
 230 with ALO data peaking near June and CSU data peaking in November. The centroid height of the sodium  
 231 layer is higher in the ALO data than in the CSU data.

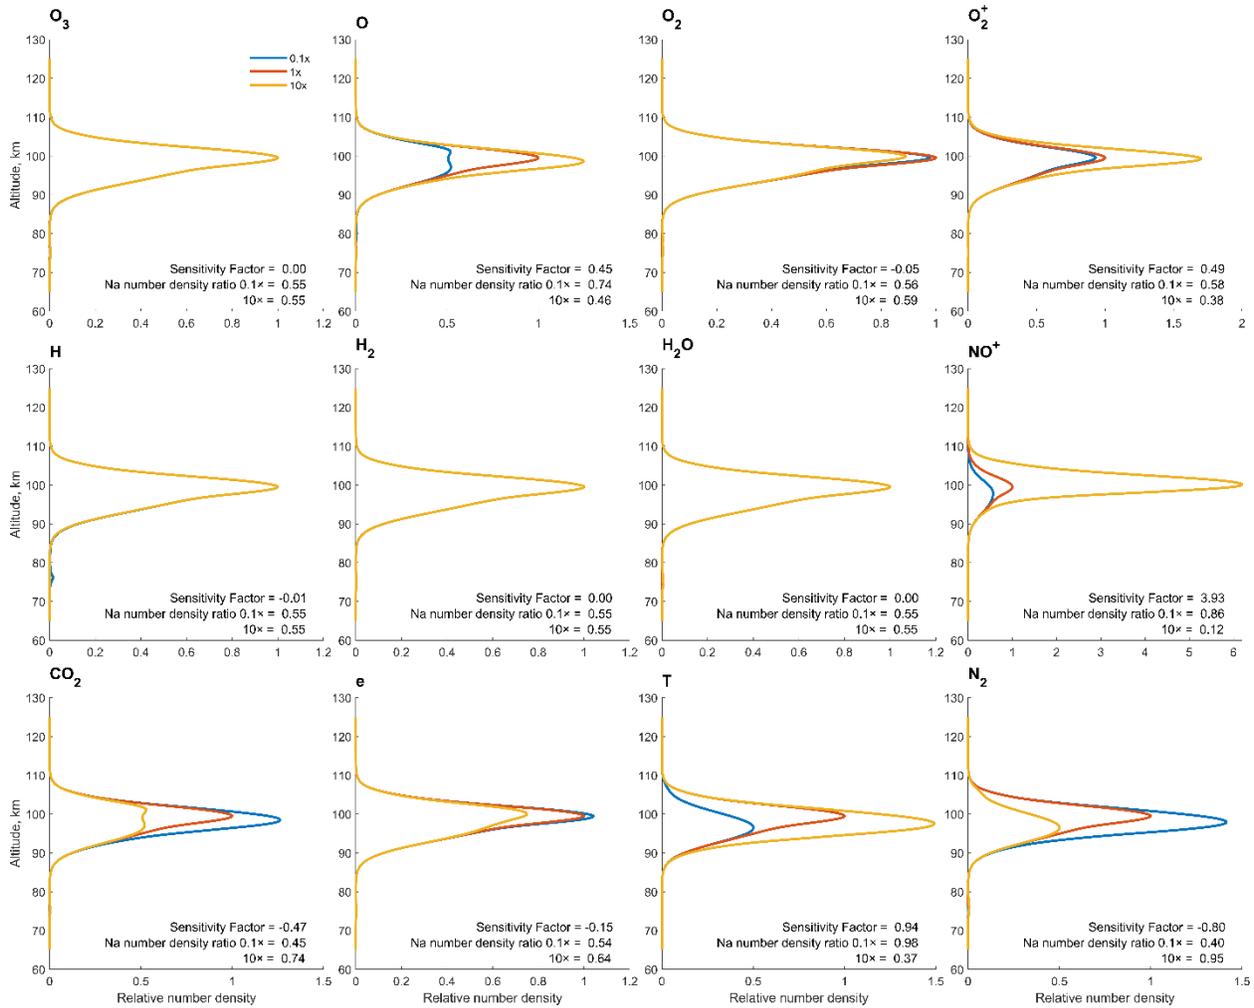

232

233 **4. Results**

234 **4.1 Sensitivity test**

235 Sodium in the atmosphere could manifest in many forms, i.e., in sodium-bearing neutral chemicals and  
236 ionic chemicals. The sodium number densities are typically obtained via lidar measurements. Given the  
237 complexity of the sodium chemistry, the observed sodium is merely a subset, possibly not even a major  
238 constituent, of the total number of all the sodium-bearing species in the atmosphere. The total sodium  
239 content is defined as the total number of sodium atoms in all 14 sodium-bearing species, as listed in  
240 Table 2. In summary, the sodium that we can detect does not necessarily provide an accurate  
241 representation of the total sodium content or the overall count of sodium-bearing species, as  
242 unobservable species such as  $\text{Na}^+$  and  $\text{NaHCO}_3$  could constitute a substantial portion of the total sodium  
243 content.

244 Understanding the impact of each background species, i.e., species listed in Figure 3., on the total  
245 sodium content is essential to study the underlying mechanism of the chemical reactions. Therefore, we  
246 present a sensitivity test by isolating variables. The sensitivity test is done by altering the number  
247 density of background species in question by two orders of magnitude, i.e., with a factor of 0.1 and 10,  
248 while keeping the number densities of other background species and the atomic sodium fixed. The  
249 simulation is kept running until all the numbers are stable. The diurnal variations of the sodium and  
250 background species are not considered in sensitivity test as they introduce unnecessary complexity. The  
251 results of the sensitivity test of the 11 background species and temperatures involved in the numerical  
252 simulation are shown in Figure 3. Each panel contains three lines, where the red curve shows the  
253 unaltered vertical profile of the total sodium content. The results of the species altered by the factor of  
254 0.1 and 10 are shown in light blue and yellow, respectively.

255

256 **Figure 3.** Sensitivity test of 11 background species and temperature on Na chemistry. The total sodium  
 257 content vertical profile for the respective background species altered by 10x and 0.1x are shown in yellow  
 258 and light blue. The reference sodium content vertical profiles are shown in red. Additionally, the  
 259 sensitivity factor and the Na number density ratio to the concentration of all sodium species are  
 260 presented on each panel.

261

262 In Figure 3, only the yellow curve is visible in some of the panels because the three curves are drawn on  
 263 top of each other, indicating that the change of the respective background species bears little to no  
 264 effect on the sodium chemistry. A sensitivity factor is defined to better quantify the weight of each  
 265 background species in sodium chemistry. The factor is calculated by the following equation:

266

$$\text{Sensitivity Factor} = \frac{NaT_c^{10} - NaT_c^{0.1}}{NaT_c} \quad (2)$$

267 Where  $NaT_c^{10}$  is the column density of the total sodium content with the respective species altered by a  
 268 factor of 10, and  $NaT_c^{0.1}$  is the same operation as the previous one but altered by a factor of 0.1. The  
 269 denominator,  $NaT_c$ , is the column density of the reference profile. The sensitivity factor provides a  
 270 general insight into how variations in the background species correlate with sodium number density. A

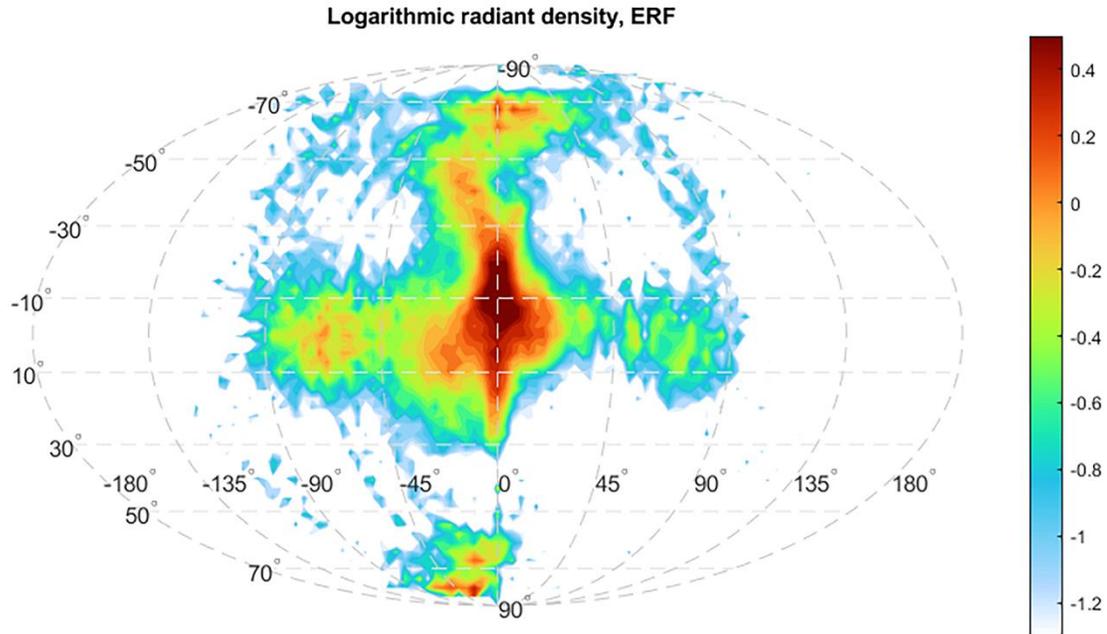

271 greater absolute value for the sensitivity factor indicates a stronger correlation. A positive sensitivity  
272 factor indicates a positive correlation between the total sodium content and the respective species, and  
273 vice versa. The reference profile is the total sodium content in steady-state in the background condition  
274 of the midnight new year of 2002, giving a typical sodium vertical profile similar to the one shown in  
275 Figure 5 of Plane (2004). In the simulation, a greater total sodium content implies that a smaller  
276 percentage of the sodium chemicals are present as sodium atoms as the altitude profile of the sodium  
277 atoms is fixed in the sensitivity test. In reality, instead of the sodium atoms, the total sodium content  
278 should be more or less conserved. Hence a higher total sodium content in our simulation suggests less  
279 sodium can be detected by the lidar.

280 Although the sensitivity factor could be different upon the change of the reference profile, it still gives  
281 an insight into the significance of each background species to the sodium chemistry. Apparently, the  
282 weight of some background species, namely  $O_3$ , H,  $H_2$ , and  $H_2O$ , is negligible in sodium chemistry,  
283 meaning that removing these species and their associated reactions has no effect on the overall sodium  
284 chemistry. Nevertheless, these species are still kept in our numerical model for completeness. The  
285 impact of species that convert Na atom to  $Na^+$ , as listed in reactions 27 and 28 of Table 1, is generally  
286 strong. The effect of  $NO^+$ , in particular, is the most significant according to the sensitivity factor, greater  
287 than the combined effect of all the other species. Consequently, the number density of the observable  
288 [Na] atom by lidar is strongly anti-correlated with the fluctuations of the  $NO^+$ . In a nutshell, more  $NO^+$   
289 will directly lead to fewer observable Na atoms. That being said, the interaction between sodium and  
290 background species is rather complex. The scope of the sensitivity factor in the present paper was  
291 limited to column density. As a result of such, variations and behaviors of the sodium chemicals by  
292 altitude are overlooked. The actual impact of the background species may differ at different altitudes.

#### 293 **4.2 Meteor input function**

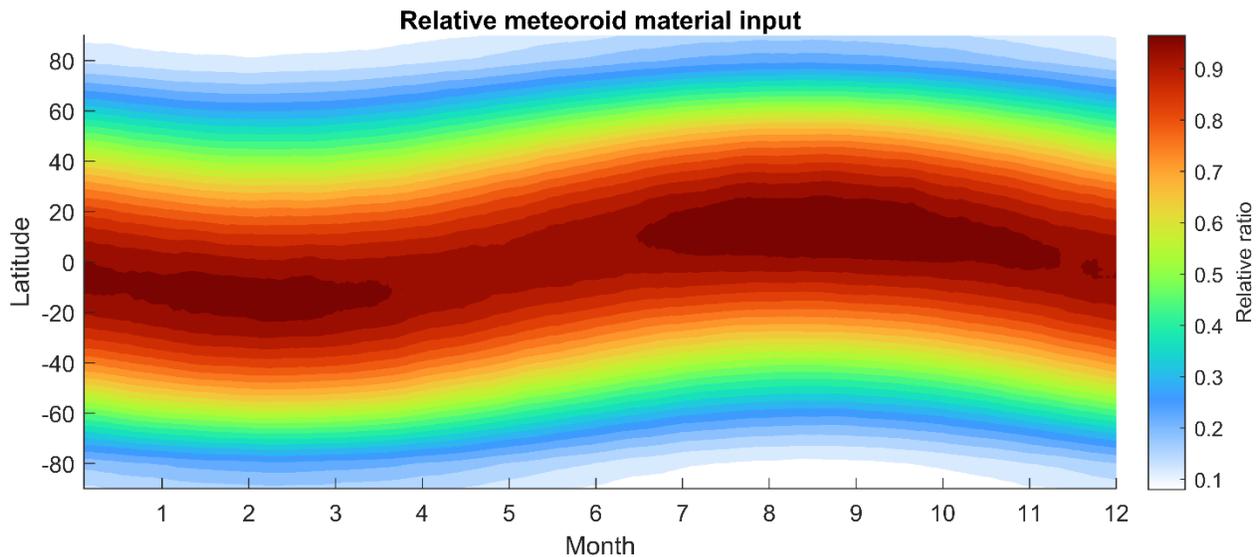

294 The estimation of meteoric influx is subject to many uncertainties among different techniques (Li et al.,  
295 2022). Moreover, the meteor flux estimated by the sodium chemistry model also varies (Marsh et al.,  
296 2014; Plane et al., 2015). The previous model of Plane (2004) and the following similar models indicate  
297 that the rate of dimerization, or the speed of removing sodium from the system, is heavily correlated to  
298 the vertical transport in the MLT. The NaChem model does not explicitly incorporate vertical transport,  
299 but the vertical transport by diffusion is inherently embedded within the input of the observed sodium  
300 vertical profile.

301 Unlike the previous models (Plane 2004; March et al. 2014; and references therein), the present  
302 NaChem model took an indirect route to estimate the meteor mass input. During the simulation, the  
303  $NaHCO_3$  dimerization and the uptake of the sodium species on meteoric smoke particles, which can be  
304 turned on or off, create a deficit of sodium atoms. Meanwhile, a meteor input function injects an  
305 appropriate amount of sodium atoms so that the present sodium vertical profile always matches the  
306 reference profiles. This is carried out by finding the difference between the current sodium profile (with  
307 the deficit) and the corresponding reference profile in every iteration and then replacing the former  
308 with the latter. The diffusion coefficient is found to be highly correlated with the sodium sink due to the  
309 dimerization reaction mostly occurs at lower altitudes. (Plane, 2004). The simulation circumvents this  
310 uncertainty by directly incorporating the observational sodium vertical profile, given that diffusion is  
311 already inherently in the measurements.

312

313 **Figure 4.** Logarithmic meteor radiant source distribution derived from the AO observations. The figure  
 314 illustrates the relative frequency of meteor occurrence at different radiant directions in the Earth  
 315 Reference Frame (ERF), equivalent to ground-based observations. The latitude of the ERF is centered on  
 316 the ecliptic plane. The longitude of the ERF is centered to the Apex direction, the moving direction of the  
 317 Earth, where the highest number of meteors encounter Earth. The radiant distribution is derived from the  
 318 number of meteor events. Figure reproduced from Li et al. (2022).

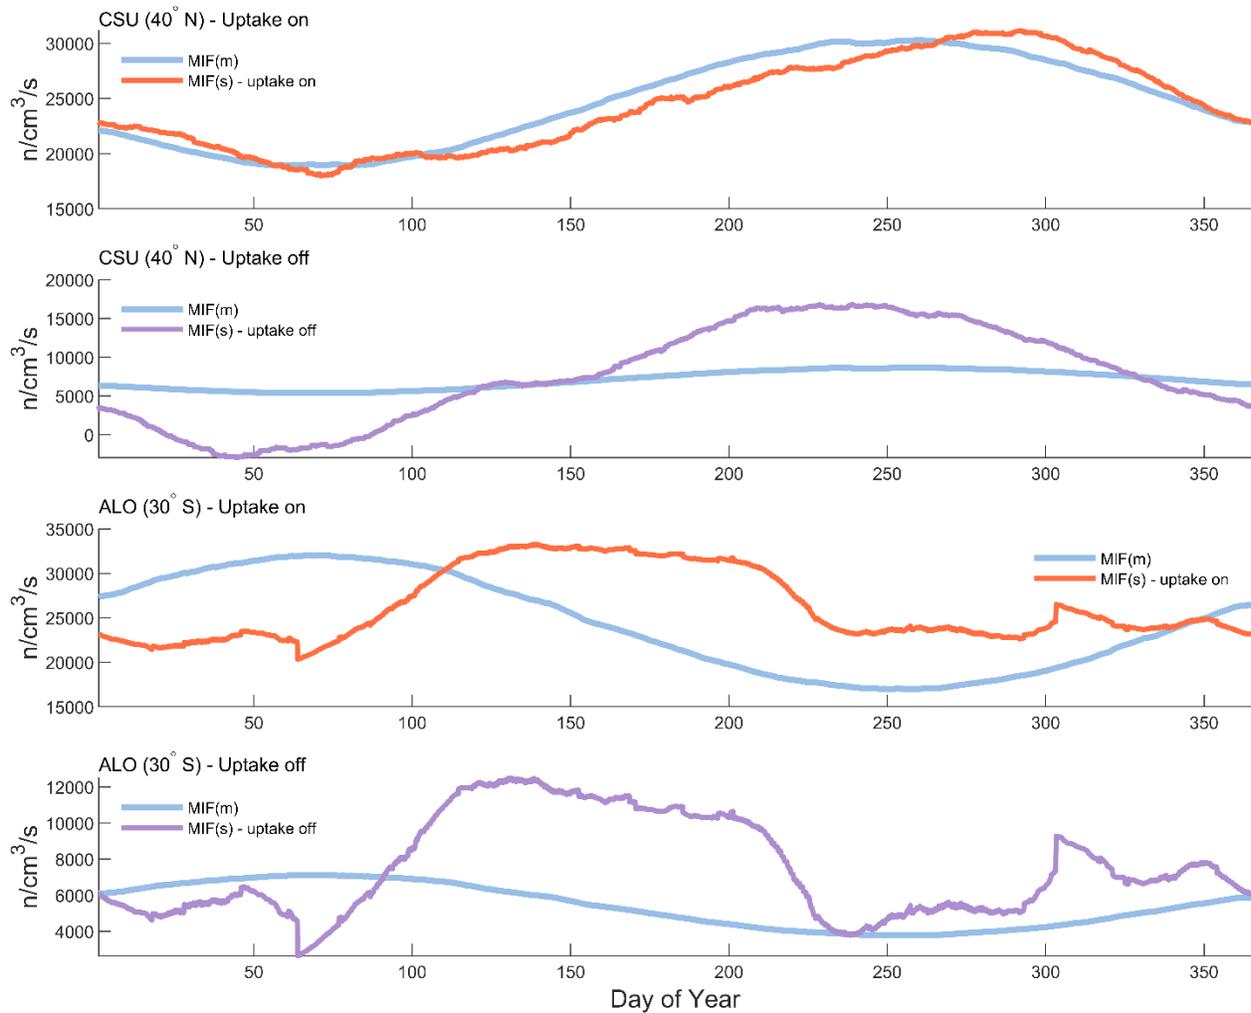

319

320 **Figure 5.** Relative seasonal and latitudinal meteoroid input by meteor occurrence, inferred from the  
 321 radiant source distribution shown in Figure 4.

322

### Sodium column injection rate

323

324 **Figure 6.** A comparison between two meteor input functions:  $MIF(m)$ , which is inferred from micro-  
 325 meteor radiant distribution, and  $MIF(s)$ , which is derived using a Na chemistry model with sodium input  
 326 from lidar observations.

327

328 Figure 4 shows the high-resolution meteor radiant source distribution recently inferred from the AO  
 329 observations (Li et al., 2022). The typical mass of the Arecibo meteors is estimated to be around  $10^{-13}$  kg  
 330 based on flux rate (Li and Zhou, 2019). Mathews et al. (2001) estimated the limiting meteor mass of  $10^{-14}$   
 331 kg based on the meteor ballistic parameter. Limiting mass is the smallest mass a meteoroid must have  
 332 to generate sufficient ionization to be detected by radar. Despite these estimations being based on  
 333 various simplified assumptions that may lead to inaccurate results, the estimated limiting mass at AO is  
 334 still at least two orders of magnitude smaller than the estimations of other facilities by similar means.  
 335 More than 95% of the meteoroid population in the Earth's atmosphere is found to be sporadic meteors  
 336 by HPLA radar observation (Chau and Galindo, 2007), which typically are low-mass meteors evolved  
 337 from the outer Solar system due to the Poynting-Robertson drag (Nesvorný et al., 2011; Koschny et al.,  
 338 2019). That being said, the percentage of sporadic meteors, as well as the radiant source distribution,

339 are both estimated based on the occurrence. However, the occurrence of sporadic meteors may not be  
340 able to represent their mass distribution. The relative seasonal and latitudinal meteoroid input by the  
341 number of occurrences inferred from the new radiant distribution is depicted in Figure 5. The meteoroid  
342 input generally follows a sinusoidal pattern and differs from the one used in the previous work, as  
343 shown in Figure 1 of Marsh et al. (2013). Although the interplanetary dust (meteor) background on the  
344 Earth's orbit could vary in different locations due to a variety of reasons, e.g., Jupiter resonance, it is still  
345 safe to assume no change in the interplanetary dust background for our purpose. Taking a stable  
346 interplanetary dust background, the MIF(m) 's seasonal sinusoidal pattern should follow the Earth's axis  
347 rotation.

348 Figure 6 shows a comparison between two types of meteor input function: MIF(m), which is inferred  
349 from the micro-meteor radiant distribution, and MIF(s), which is derived using the Na chemistry model  
350 with sodium input from the lidar observations. For the MIF(s) model simulations, we did two scenarios,  
351 one with and one without uptake by smoke particles, for the ALO and CSU data. The MIF(s) with uptake  
352 by smoke particles exhibit a good match with the MIF(m) on the CSU dataset, while it does not show as  
353 good of a match on the ALO dataset. The MIF(s) with smoke uptake on is represented by a purple line,  
354 while the MIF(s) with smoke uptake turned off is depicted by an orange line. The MIF(s) could go  
355 negative when the reference sodium vertical profile decreases faster than the removal rate by the  
356 dimerization, as shown in the orange line in Figure 6, indicating that the dimerization process alone is  
357 not sufficient enough to account for all the sodium atom depletion in the MLT region. MIF(m) is derived  
358 from a global micro-meteor radiant distribution model, as depicted in Figure 4 and Figure 5. The smoke  
359 uptake of sodium species in this study is implemented using a methodology similar to Plane (2004), but  
360 instead of applying smoke uptake solely to the three major sodium species, namely Na, NaHCO<sub>3</sub>, and  
361 Na<sup>+</sup>, it is applied to all 14 sodium-bearing species. The optimal uptake factor to obtain the best results  
362 was found to be  $2 \times 10^{-2}$ /km/s. The smoke uptake and NaHCO<sub>3</sub> dimerization account for approximately  
363 75% and 25% of the Na sink, respectively.

364 According to the global meteoroid orbital model outlined in Li et al., (2022), the latitudes spanning 29.5°  
365 S to 30.5° S (ALO) account for 0.52% of the total meteor input, while those between 39.5° N and 40.5° N  
366 (CSU) represent 0.67%. The CSU site shares more meteor input due to its closer proximity to one of the  
367 Apex meteor radiant sources. The global total sodium injection rate inferred from the ALO data-based  
368 simulation is  $2.01 \times 10^{23}$  atoms per second, and the CSU-data-based simulation suggests a global sodium  
369 injection rate of  $1.28 \times 10^{23}$  atoms per second. Assuming the relative sodium elemental abundance in  
370 meteoroid material is 0.8% (Vondrak et al., 2008), the deduced total meteoroid material input of ALO-  
371 based simulation was  $83 \text{ t d}^{-1}$ . From CSU-based simulation, the rate is  $53 \text{ t d}^{-1}$ . Both estimations are close  
372 to  $80\text{-}130 \text{ t d}^{-1}$ , the value reported by the Long Duration Exposure Facility (Love and Brownlee, 1993;  
373 McBride et al., 1999). It is worth noting that the estimated total daily input of meteoroid materials  
374 varies among previous studies, ranging from  $4.6 \text{ t d}^{-1}$  (Marsh et al., 2013) to  $300 \text{ t d}^{-1}$  (Nesvorný et al.,  
375 2009), with an intermediate value of  $20 \text{ t d}^{-1}$  reported by Carrillo-Sánchez et al. (2020). While these  
376 estimates seem quite disparate, the variance is relatively small given that the daily input rate is derived  
377 from combinations of chemicals that can fluctuate by several orders of magnitude. For example, the  
378 NO<sup>+</sup>, which exhibits the highest sensitivity factor according to the sensitivity test, undergoes diurnal  
379 variations of approximately three orders of magnitudes.

380

## 381 5. Discussion

382 The sodium concentration in the sodium layer in the MLT region is governed by several factors, including  
383 chemistry, dynamics, and the MIF. It's difficult to discern which of these three components is more  
384 important than the others. In this section, we discuss various factors that may contribute to modeling  
385 the sodium concentration in the MLT.

386 The mass of the meteoroids has been estimated and measured using various methods. These include  
387 the ballistic parameter derived from meteor deceleration (Mathews et al., 2001), estimation of meteor  
388 head echo plasma distribution through a combination of meteor ablation models and radar cross-  
389 section measurements (Close et al., 2005; Sugar et al., 2021), flux rate determination (Zhou and Kelley,  
390 1997), as well as spacecraft in-situ measurements (Leinert and Grun, 1990), among others. The mass  
391 estimated by the meteor ballistic parameter is commonly referred to as momentum or dynamical mass.  
392 The mass estimated by the meteor ablation model is usually called the scattering mass. The meteor  
393 momentum mass from Arecibo Ultra-High-Frequency (UHF) radar observation is estimated to be  $10^{-14} -$   
394  $10^{-7}$  kg, with the typical mass being  $10^{-13}$  kg. On the other hand, the meteor scattering mass is estimated  
395 to be  $10^{-9} - 10^{-5.5}$  kg by data from EISCAT UHF radar (Kero et al., 2008) and  $10^{-7} - 10^{-4.5}$  kg by data from  
396 ALTAIR UHF radar (Close et al., 2005). While the detection sensitivity among different facilities differs,  
397 these estimations are still off by many orders of magnitude. The assessments of either momentum mass  
398 or scattering mass are based on a variety of simplified assumptions. They are subject to errors due to  
399 the complexity of radar beam patterns, background atmosphere conditions, aspect sensitivity, meteor  
400 radiant sources, and many other possible factors. For example, radar meteor observation is subject to  
401 bias against low-mass, low-velocity meteors (Close et al., 2007; Janches et al., 2015).

402 Another aspect that may contribute to the MIF(m)'s uncertainty is the meteor radiant distribution. The  
403 meteor radiant distributions shown in Figure 4 and many others (Chau et al., 2004; Campbell-Brown and  
404 Jones, 2006; Kero et al., 2012) are inferred or measured by meteor occurrence instead of mass input.  
405 Currently, retrieving a more accurate estimation of the meteor mass input is still a topic under active  
406 research, and there is no quantitative study on the disparities between meteor occurrence and meteor  
407 mass input. The radiant sources of the meteors are expected to differ by mass as their orbital evolution  
408 is highly correlated to their mass. The interplanetary dust interacts with the solar wind while in the Solar  
409 System, losing its momentum in the process and evolving into orbits with a smaller semi-major axis and  
410 lower eccentricity. The effect is called the Poynting-Robertson effect (Robertson and Russell, 1937),  
411 which behaves like a drag force and defines the evolution of interplanetary dust, and it could be the  
412 major reason for the existence of sporadic meteors (Li and Zhou, 2019; Koschny et al., 2019). The  
413 importance of the Poynting-Robertson effect is highly dependent on the density and mass of the object.  
414 By and large, the orbits of the smaller particles evolve exponentially faster. The orbital dynamics of  
415 interplanetary particles have been very well summarized in section 2.2 of (Koschny et al., 2019). For the  
416 reasons above, the meteor radiant distribution of mass could deviate from the radiant distribution of  
417 occurrence. Therefore, the meteor input rates as shown in the blue curves of Figure 6 could be different  
418 from those derived from the meteor radiant distribution of mass since they were derived from the  
419 meteor radiant distribution by occurrence.

420 In the sodium chemistry model presented in this work, the MIF is the sole source of sodium, while the  
421 sodium sink comprises  $\text{NaHCO}_3$  dimerization and smoke uptake. The MIF(s) is determined by matching  
422 the sink rate of the sodium atoms with the rate of sodium injection. In other words, MIF(s) represents

423 the amount of sodium injection needed to keep the sodium concentration equal to the reference  
424 sodium profiles. If the chemical lifetime of sodium in the MLT is short, then the seasonal variation of  
425 both the MIF and sodium concentration in the MLT should be similar. After examining Figures 3, 5, and  
426 6, it can be observed that the averaged seasonal variation of sodium over the years at both sites (ALO  
427 and CSU) does not correspond to the trend of the MIF(m) at their respective latitudes. This may indicate  
428 that the chemical lifetime of sodium in the MLT should be relatively long, as there is no immediate effect  
429 of MIF(m) on the sodium concentration. The MIF displays a sinusoidal pattern which peaks in March at  
430 the ALO's latitude and in August at the CSU's latitude, whereas the sodium layer shows dual peaks in the  
431 CSU's lidar observations and one peak in June in the ALO's lidar observations.

432 In this study, the MIF(s) derived from the NaChem simulation, based on the CSU lidar measurements  
433 with uptake turned on, was able to match the amplitude of MIF(m) obtained from the meteor radiant  
434 distribution. Although the model does not directly incorporate any dynamical processes, the vertical  
435 transport by diffusion is implicitly included. The model forces the sodium layer to be the same as the  
436 data, which are averaged by the observations of many years, in which the diffusions are inherently  
437 embedded. The combination of observational data with the numerical chemistry model in this paper is a  
438 relatively straightforward application of data assimilation (Bouttier & Courtier 2002). The lidar data of  
439 both sites (CSU and ALO) indicate that the sodium column density consistently increases by about 20%  
440 from 22:00 to 4:00 LT the next day. This can be attributed to the fact that, during nighttime, the large  
441 deposits of  $\text{Na}^+$  formed by daytime reactions slowly neutralized to Na. As a result, the sodium column  
442 density consistently increases throughout the night. The same effect can be reproduced in the NaChem  
443 simulation, albeit with a smaller amplitude. The simulation shows the increase to be about 8%. The  
444 value is obtained by maintaining a constant total number of sodium-bearing species through the  
445 deactivation of the sodium sink.

446 While meridional transport or atmospheric dynamics both contribute to the seasonal variation of the  
447 sodium layer in the MLT, the diurnal sodium profile is the mean of observations of thousands of days, of  
448 which the variation by atmospheric dynamics should be much less prominent. The lack of explicit  
449 dynamics in the model may be one of the sources of inconsistency when compared to the observations.  
450 Further, the WACCM 6, which supplied the background species to the NaChem, is an older version that  
451 does not fully incorporate the dynamics of each ion species. Despite our results showing good  
452 agreement between the MIF(s) and the MIF(m), there might be several plausible factors that could lead  
453 to potential errors. For example, the Na sink by  $\text{NaHCO}_3$  dimerization varies by the diffusion rate or the  
454 vertical transport of sodium atoms in the chemistry model (Plane, 2004). Likewise, the MIF(m) may also  
455 differ if the meteoroid mass input differs from the radiant source distribution by the occurrence of  
456 meteors, as discussed in the aforementioned paragraph.

## 457 **5. Conclusion**

458 This work introduced a new sodium chemistry model that simulates the time evolution of all sodium-  
459 bearing species using the continuity equation without making any steady-state assumption. The model  
460 employs an exponential integrator and runs in high-time resolution to maintain numerical stability. The  
461 model is simple to maintain in such a configuration and can be scaled up to include additional  
462 capabilities more easily. The model is highly optimized for processing efficiency and benefits from the  
463 use of an exponential integrator. Therefore, within an acceptable total CPU time, the NaChem can afford  
464 a time resolution of up to milliseconds, several orders of magnitude smaller than those used in other Na

465 models. During our testing, the CPU time to simulated real-time ratio is about 1 to 1000 using a 0.1  
466 second time step.

467 The model simulation was able to reproduce the seasonal variation of the sodium layer in the MLT by  
468 simulations of chemical reactions. The simulation results at the CSU's latitude capture the general trend  
469 of the seasonal variation at the location. The MIF(s) based on the ALO data exhibited less conformity  
470 with the corresponding MIF(m), which could be attributed to inadequate statistics of the observational  
471 data. Comparably, the CSU dataset is more reliable as the insufficient lidar hours in the ALO dataset may  
472 lead to inaccurate statistics. In the simulation, when forcing the sodium layer to be the observation-  
473 based reference profile, the inferred MIF is estimated to be  $83 \text{ t d}^{-1}$  at ALO and  $53 \text{ t d}^{-1}$  at CSU. The  
474 numerical simulation by NaChem could reproduce the general trend of diurnal and seasonal variation of  
475 the sodium layer compared to the observations by the CSU Lidar. There are some inconsistencies in  
476 MIF(m) and MIF(s) based on data obtained from ALO Lidar. These inconsistencies may have originated  
477 from poor statistics resulting from insufficient observation hours.

478 In summary, a new sodium chemistry model has been developed in this work to investigate the  
479 relationship between MIF and the sodium layer. We also compared the MIF(m) derived from radar  
480 meteor observation to the MIF(s) derived from the chemistry model and lidar observations. Our results  
481 indicate that the uptake of sodium species onto meteoric smoke particles removes approximately three  
482 times more sodium than the dimerization of  $\text{NaHCO}_3$ . Our future work will focus on incorporating the  
483 plausible factors that may lead to potential errors discussed above into the chemistry model.

485

#### 486 Acknowledgment

487 The study is supported by NSF Grant AGS-1903346. T.-Y. Huang acknowledges that her work is supported  
488 by (while serving at) the National Science Foundation. WF was supported by the UK Natural Environment  
489 Research Council (grant no. NE/P001815/1). Any opinions, findings, and conclusions or recommendations  
490 expressed in this material are those of the authors and do not necessarily reflect the views of the National  
491 Science Foundation. The lidar data used in this paper are obtained from The Utah State University (USU)  
492 Sodium LIDAR facility and the Andes Lidar Observatory.

493

#### 494 Code/Data availability

495 The CSU lidar data is available through Utah State University data service (Yuan, 2023). The ALO data is  
496 available through the ALO online database (ALO, 2023). The WACCM data used in this work are available  
497 through Penn State Scholarsphere (Li, 2023b).
