

Investigating the Role of Gravity Waves on Mesosphere-Lower-Thermosphere

(MLT) Inversion Layers at Low Latitudes (3-15°)

Abstract

The Mesosphere and Lower Thermosphere (MLT) transitional region, encompassing a height range of 60-100 km, is a distinct and highly turbulent zone within the Earth's atmosphere. This region is particularly significant due to dynamic processes like gravity waves, which contribute to the formation of the Mesospheric Inversion Layer (MIL). Investigating these phenomena is crucial for understanding the dynamics of the middle and upper atmosphere, especially regarding stability and energy transfer. Inversion layers significantly influence the stability of the atmosphere in this region, playing a crucial role in atmospheric dynamics. Inversion layers are associated with energy transfer processes, vital for understanding the overall dynamics of the atmosphere. Despite extensive study on an inversion, the formation mechanisms of mesospheric inversions remain poorly understood. This article explores the upper and lower inversion phenomena and their causative mechanisms. It uses long-term SABER observations from 2005 to 2020 over the latitude range of 3-15° N and longitude range of 33-48° E. The results show that the upper inversion occurs more frequently, with a frequency below 40%, compared to the lower inversion, which occurs below 20%. The upper inversion occurs within the height range of 78-91 km, with an inversion amplitude of approximately 20-80 K and a thickness of around 3-12 km. In contrast, the lower inversion is confined to the height range of 70-80 km, with an inversion amplitude of about 10-60 K and a thickness of around 4-10 km. Moreover, the gravity wave indicator potential energy shows high energy (below 100 J/kg) in the upper mesosphere region (85-90 km) compared to the lower mesosphere region (70-75 km) with less than 50 J/kg. Considering gravity waves, the Brunt-Väisälä frequency (N^2) stability criteria indicate instability in the upper mesosphere region with very low values compared to the lower mesosphere region. This suggests that the high amount of gravity wave potential energy is a consequence of the higher instability in the upper inversion compared to the lower inversion.

Keywords: Mesosphere and Lower Thermosphere (MLT), Upper and Lower Inversions, Perturbed Temperature, Causative Gravity Waves, Potential Energy, Brunt-Väisälä Frequency, Atmospheric Instability.

34 **Introduction**

35 The Mesosphere and Lower Thermosphere (MLT) region serves as a transitional zone for wave
36 processes from the lower and upper atmospheres, including tidal, planetary, and gravity waves.
37 Gravity waves (GWs) originating from the lower atmosphere are known to propagate into the
38 mesosphere. There, they break and dissipate their energy and momentum, affecting the thermal
39 structure, global atmospheric circulation, and variability of the mesosphere. This process also
40 influences the formation of mesospheric inversion layers (MILs), which are associated with
41 increased temperature variability in the mesosphere. MILs indicate wave saturation when the lapse
42 rate falls below the dry adiabatic lapse rate (Sica et al., 2007). Temperature inversions in the
43 mesosphere have been widely observed and studied using various techniques, including lidar,
44 radar, rocket sondes, and satellites, across different geographic locations. Sivakandan et al. (2014)
45 utilized TIMED/SABER kinetic temperature data to examine the occurrence and characteristics of
46 mesospheric inversions over the equatorial Indian region (0 to 10° N and 70 to 90° E) for the years
47 2002 and 2008. However, they did not explore the causative factors. This study aims to investigate
48 the causes of these inversions, focusing specifically on the role of atmospheric gravity waves.

49 Gravity waves and mesospheric inversion layers (MILs) are interconnected phenomena within the
50 Earth's atmosphere, particularly in the mesosphere and lower thermosphere. MILs are layers within
51 the mesosphere where the temperature profile shows an inversion. This means the temperature
52 increases with altitude, contrary to the typical decrease. These inversion layers often form due to
53 dynamic processes, including the breaking and dissipation of gravity waves. As gravity waves
54 propagate upwards, they can grow in amplitude because the atmospheric density decreases with
55 altitude. When these waves reach a critical amplitude, they become unstable and break. This
56 breaking process releases energy and momentum into the surrounding air, causing localized
57 heating. The energy dissipation from breaking gravity waves causes localized heating. This heating
58 can create or enhance mesospheric inversion layers by increasing the temperature at certain
59 altitudes. The breaking of gravity waves can also generate turbulence, which further influences the
60 structure and stability of inversion layers. This process also contributes to momentum and energy
61 deposition.

62 The momentum and energy deposition of gravity waves (GWs) are believed to be key drivers of
63 large-scale atmospheric circulation, the coupling of different atmospheric layers, and inversion
64 phenomena (Fritts and Alexander, 2003; Lindzen, 1981; Smith, 2012). Additionally, researchers
65 are exploring the influence of gravity wave-breaking on mesosphere dynamics to understand its

66 impact on inversion phenomena, particularly in mid- and high-latitude regions (Gan et al., 2012;
67 Walterscheid and Hickey, 2009; Collins et al., 2011; Szewczyk et al., 2013). Both observational
68 and modeling studies have investigated GWs as a cause of these inversions (Fritts, 2018; Collins
69 et al., 2014; Sridharan et al., 2008; Ramesh and Sridharan, 2012; Ramesh et al., 2013, 2014, 2017).
70 Despite extensive exploration, our understanding of the impact of gravity waves on mesosphere
71 inversions, particularly in terms of temperature variability, remains incomplete, especially in mid-
72 and high-latitude regions (Singh and Pallamraju, 2018; Fritts et al., 2018). As a result, the study of
73 inversion phenomena and their underlying causes remains a key area of focus in mesosphere
74 dynamics research.

75 Research on the temporal and spatial variability of the mesosphere inversion phenomenon,
76 particularly about atmospheric waves and gravity wave activity, is notably lacking in low latitudes.
77 To address this gap, our study investigates the mesosphere inversion phenomenon and its
78 association with gravity wave activity and stability criteria. We use Brunt-Vaisala frequency (N^2)
79 over the low latitudinal band (3° – 15° N) with long-term SABER observations from 2005 to 2020.
80 The study is organized as follows: Section 2 details the data and methodology used to analyze the
81 mesosphere inversion phenomenon and their causative gravity waves via the potential energy.
82 Section 3 presents the results, and Section 4 concludes the findings.

83 **2. Observation and Data analysis**

84 **2.1 SABER Observation**

85 The TIMED/SABER satellite, launched on December 7, 2001, operates in an elliptical orbit at
86 approximately 625 km altitude with a 74° inclination relative to the equator. Since its launch,
87 SABER has been a crucial tool for atmospheric research, providing extensive data on the middle
88 atmosphere. SABER is a limb-viewing radiometer working in the infrared region (1.27–17
89 microns) and can measure radiative emissions across a wide range of altitudes. It offers nearly
90 global coverage and continuous 24-hour data over 60 days. The instrument completes 15 orbits
91 daily, each taking about 97 minutes, and collects around 1400 data profiles per day, with each
92 profile taking 58 seconds. SABER's high-resolution temperature profiles are essential for studying
93 the dynamics and wave processes in the mesosphere. It provides temperature measurements with
94 an accuracy of 1 to 2 K between 15 and 60 km. The accuracy decreases to 5 K below 85 km and
95 increases to 6.7 K to 10 K near 100 km. This data has been instrumental in understanding the
96 thermal structure and dynamical processes in the mesospheric region, as highlighted by various
97 studies (Garcia et al., 2008; Gan et al., 2012, 2014; Bizuneh et al., 2022; Lingerew et al., 2023;

98 Rezac et al., 2015; Meriwether and Gerrard, 2004; Fechine et al., 2008; Dou et al., 2009; France
99 et al., 2015).

100 We utilized SABER vertical temperature profiles taken within the 60–100 km altitude range. These
101 profiles cover the period from 2005 to 2020, spanning latitudes from 3°N to 15°N and longitudes
102 from 33°E to 48°E. Figure 1 shows the monthly mean of SABER temperature data for the
103 mesosphere and lower thermosphere. The data aim to illustrate the MLT temperature variability,
104 which helps us identify the inversion layers (MIL). The monthly mean temperatures in the MLT
105 region show a maximum of 200-240 K at altitudes of 60-70 km. Then it decreases to around 160-
106 180 K at 95-100 km throughout the entire period. While the temperature patterns in the 70-90 km
107 altitude range suggest an inversion, these inversions are not visible.

108 **Figure 1.** The monthly mean of MLT temperature variability in the height range of 60-100 km
109 during 2005-2020 over the low-latitude.
110

111 2.2 Analysis Technique

112 The Earth's middle atmosphere typically has a negative temperature gradient, but some reports
113 have shown positive temperature gradients in the mesosphere (Meriwether and Gardner, 2000;
114 Gan et al., 2012). This phenomenon is called the “mesospheric inversion layer (MIL)”. MILs are
115 identified using a procedure detailed by Leblanc and Hauchecorne (1997) and Fechine et al.(2008).
116 Mesospheric inversions are characterized by their thickness (the altitude difference between
117 maximum warming and cooling) and amplitude (the temperature difference between these points)
118 (Meriwether and Gardner, 2000). Here are the identification criteria for these inversions:

- 119 1. The bottom level of the lower inversion is above 70 km, and the top level is below 80 km.
- 120 For the upper inversion, the bottom level is above 80 km, and the top level is below 92 km.
- 121 2. The amplitude is considered larger than 5 K.
- 122 3. The thickness is greater than or equal to 3 km.

123
 124 Figure 2. Schematic of upper and lower mesospheric inversion layers shown in the temperature
 125 profile for the MLT regions (Adapted from Meriwether and Gerrard, 2004).

126 Figure 2 illustrates this concept, showing a positive temperature difference between the top and
 127 bottom levels of the inversion. This method has been utilized in numerous previous studies
 128 investigating mesospheric inversions (Leblanc et al., 1998; Meriwether and Gardner, 2000; Duck
 129 et al., 2001; Duck and Greene, 2004; Cutler et al., 2001; Siva Kumar et al., 2001; Ratnam et al.,
 130 2003; Gan et al., 2012). The frequency occurrence rate of mesospheric inversion layers (MILs) is
 131 derived during the period 2005–2020 in the upper and lower MLT regions. This rate is calculated
 132 by dividing the number of inversion days in each month by the total number of days in that month
 133 over the 16-year observation period (2005–2020).

134 Mesospheric temperature inversions are related to instabilities in atmospheric dynamics. To
 135 identify the causative, short-period atmospheric gravity waves, a high-pass filter with a one-hour
 136 interval cutoff frequency is applied using the Brunt-Väisälä frequency (N^2). Another important
 137 concept to estimate the Brunt-Vaisala frequency is the potential temperature (θ). It represents the
 138 air parcel's temperature when it is displaced adiabatically to a standard pressure level, p_0 , from the
 139 current pressure level, p . This is based on the first law of thermodynamics.

140
$$\frac{dT}{T} = \frac{R}{c_p} \frac{dp}{p} \Rightarrow \int_T^0 \frac{dT}{T} = \int_p^{p_0} \frac{R}{c_p} \frac{dp}{p} \quad (1) \text{ it yields}$$

141
$$\theta = T \left(\frac{p_0}{p} \right)^{R/c_p} \quad (2)$$

142 Therefore, the motion of a vertical atmospheric air parcel can be described by (Liu, 2011; Vadas
143 and Fritts, 2005) as follows in equation (2.3). This equation calculates the Brunt-Vaisala frequency
144 of the parcel due to the buoyant and gravitational forces acting on it.

145
$$\frac{d^2s}{dt^2} = -g \frac{\rho - \rho_0}{\rho} \sin a \quad (3)$$

146 Based on the hydrostatic equation, $\rho = \rho_0$, and $p = p_0 \Rightarrow \frac{\partial p}{\partial z} = \frac{\partial p_0}{\partial z} = -g\rho_0$ (4) and the ideal gas
147 law, $\rho = p/RT = p_0/RT$ gives the parcels motion of an equation:

148
$$\frac{d^2s}{dt^2} = -\frac{g}{\rho} \left(\frac{d\rho}{dp} \frac{\partial p_0}{\partial z} - \frac{\partial \rho_0}{\partial z} \right) z \quad (5)$$

149 Following the same approach using the hydrostatic equation (4) and adiabatic equation (6)

150
$$d \ln \rho = \frac{d \ln p}{\gamma}, \gamma = c_p/c_v \quad (6) \text{ yields}$$

151
$$\frac{d^2s}{dt^2} = -\frac{g}{\rho} \left(\frac{\rho}{\gamma p_0} \frac{\partial p_0}{\partial z} - \frac{\partial \rho_0}{\partial z} \right) z = g \left(\frac{\partial \ln \rho_0}{\partial z} - \frac{1}{\gamma} \frac{\partial \ln p_0}{\partial z} \right) z \quad (7)$$

153 For the ideal gas law of $p = \rho RT$, the natural logarithm is taken for altitude, z on both sides, yielding

154
$$\frac{\partial \ln \rho}{\partial z} = \frac{\partial \ln p}{\partial z} - \frac{\partial \ln T}{\partial z} \quad (8)$$

155 Then after, the potential temperature (θ) of the parcel is calculated as follows based on the equation
156 (2):

157
$$\frac{\partial \ln \theta}{\partial z} = \frac{\partial \ln T}{\partial z} - \frac{R}{c_p} \frac{\partial \ln p}{\partial z} = \frac{1}{T} \left(\frac{\partial T}{\partial z} + \frac{g}{c_p} \right) = \left(1 - \frac{R}{c_p} \right) \frac{\partial \ln p}{\partial z} - \frac{\partial \ln \rho}{\partial z} \quad (9) \text{ to derive the Parcels}$$

158 acceleration based on equations (7) to become:

159
$$\frac{d^2s}{dt^2} = -g \frac{\partial \ln \theta_0}{\partial z} z \sin a = -g \frac{\partial \ln \theta_0}{\partial z} ds \cdot \sin^2 a \quad (10)$$

160 Whereas by introducing the frequency, N , with $N^2 = g \frac{\partial \ln \theta_0}{\partial z}$

161 The Brunt-Vaisala frequency, N^2 is calculated based on the following mathematical formulation
162 used to characterize atmospheric stability.

163
$$N^2(z) = \frac{g(z)}{T_0(z)} \left(\frac{\partial T_0(z)}{\partial z} + \Gamma_d \right) \quad (11)$$

164 Where g is the acceleration due to gravity, N is the Vaisala frequency, T_0 is the background
165 temperature (estimated based on third-order polynomial fitting), $\Gamma_d = g/c_p$ is the adiabatic lapse

166 rate, and $c_p = 1004 J K^{-1} kg^{-1}$ is the specific heat capacity of the atmosphere at constant
 167 pressure. When the Vaisala frequency, N^2 , is positive, the atmosphere is stable. When N^2 is
 168 negative, the atmosphere is unstable. In this case, the atmospheric lapse rate, $\Gamma = -\frac{\partial T}{\partial z}$, is larger
 169 than the adiabatic lapse rate, $\frac{g}{c_p} \approx 9.5 K km^{-1}$. To estimate the Brunt-Vaisala frequency, a
 170 third-order polynomial fit of the least squares has been applied to the SABER observed
 171 temperature (T) profile to estimate the background temperature (T_0), following the procedure of
 172 Leblanc and Hauchecorne (1997). After estimating the perturbed temperature (T_p) from equation
 173 (12), it is identified by subtracting the background temperature from the observed temperature data
 174 (T).

$$T_p = T - T_0 \quad (12)$$

176 After estimating the perturbed temperature (T_p), a high-pass band filter is applied. This filter
 177 removes low-frequency components associated with planetary and tidal waves, retaining the high-
 178 frequency components related to short-period gravity waves (John and Kumar, 2012). This process
 179 isolates the influence of gravity waves and accurately calculates their potential energy. The high-
 180 pass filter is based on known frequency ranges, typically below the periods of short-period gravity
 181 waves (e.g., <1 hour).

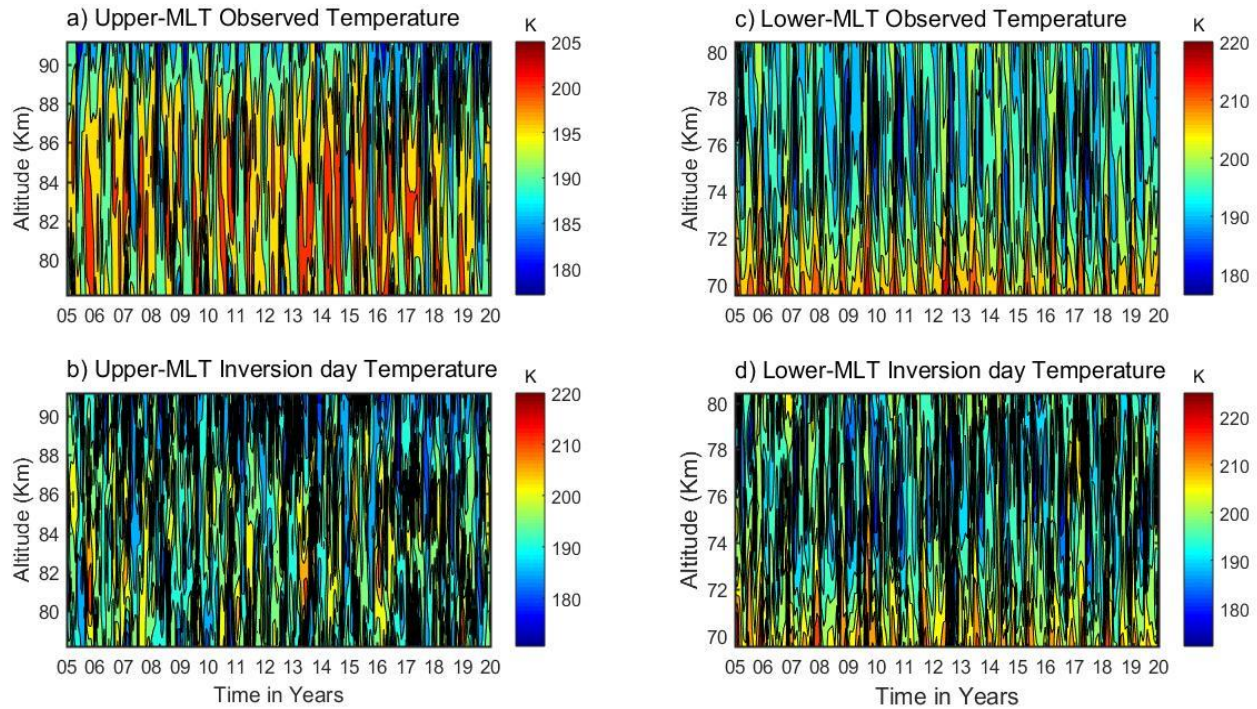

$$E_p(z) = \frac{1}{2} \left(\frac{g(z)}{N(z)} \right)^2 \left(\frac{T_p'(z)}{T_0(z)} \right)^2 \quad (13)$$

182 The potential energy of the waves, a function of altitude (z), is used to determine the impact of
 183 atmospheric gravity waves on atmospheric inversions.

185 3. Results and discussion

186 3.1 Identification and Characteristics of the Lower and Upper MLT Inversion

187 Daily SABER temperature profiles, covering altitudes of 60–100 km from 2005 to 2020, are shown
 188 in the contour plots of Figure 3. Figures 3 (a and b) depict the upper mesosphere, while Figures 3
 189 (c and d) show the lower mesosphere. The horizontal panels of Figures 3 (a) and 3 (c) show
 190 observed temperatures ranging from approximately 180–220 K, before accounting for inversion
 191 layers. The horizontal panels of Figures 3 (b) and 3 (d) show inversion day temperatures, ranging
 192 from 180–225 K. These inversion day temperatures are higher than those shown in Figures 3 (a)
 193 and 3 (c). This indicates that maximum temperatures occur on inversion days in both the upper
 194 and lower MLT regions.

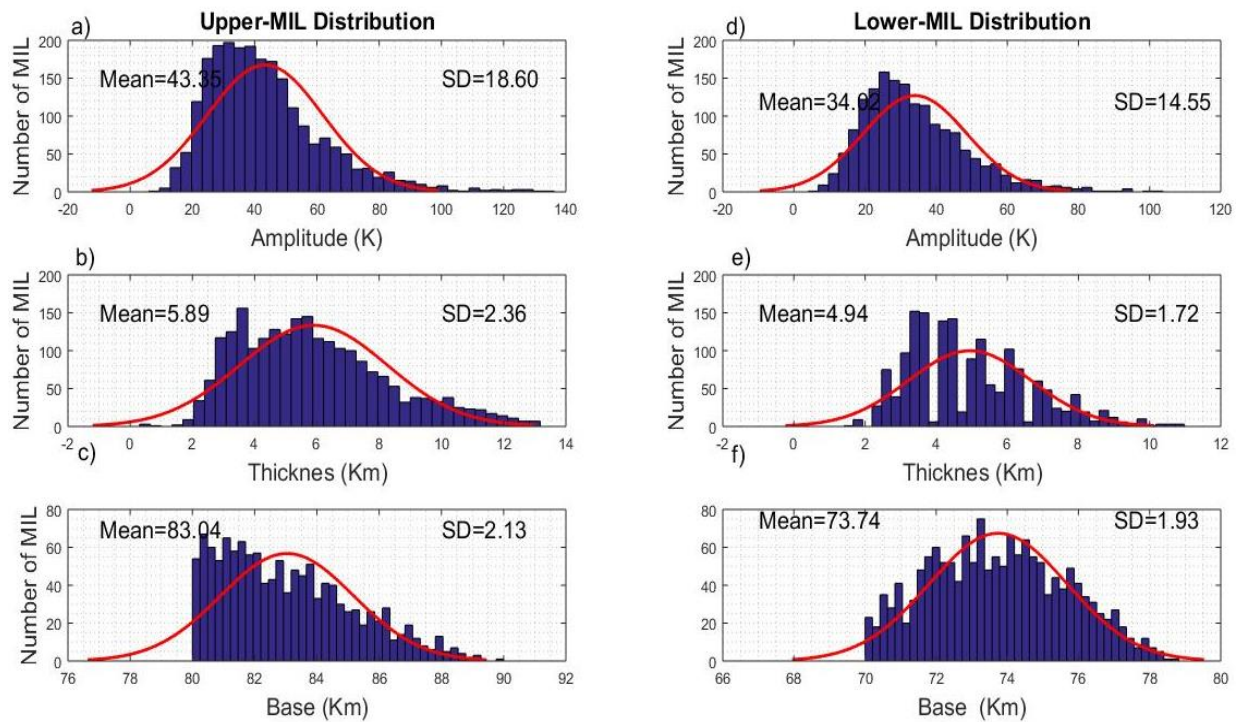

195
 196 **Figure 3.** The upper and lower mesosphere observed temperatures in the first horizontal panel at
 197 (a and c) with their inversions in the second horizontal panel at (b and d).

198 The upper left panel of Figure 3(a) shows the observed temperature in the upper mesosphere. It
 199 ranges from approximately 180–205 K at altitudes of around 80–90 km. The upper right panel of
 200 Figure 3(c) shows the lower mesosphere, with temperatures ranging from about 180–220 K at
 201 altitudes of approximately 70–80 km. In contrast, the lower left panel of Figure 3(b) shows an
 202 upper-mesosphere inversion day temperature. It ranges from 180–220 K at an altitude of
 203 approximately 80–90 km. The lower right panel of Figure 3(d) shows a lower-mesosphere
 204 inversion day temperature. It ranges from 180–225 K at an altitude of approximately 70–80 km.
 205 These inversion day temperatures in Figures 3(b) and 3(d) suggest a temperature gradient shifting
 206 from negative to positive. This could be due to factors such as atmospheric gravity waves, chemical
 207 reactions, or solar radiation. Our temperature observations for the lower MLT region on an
 208 inversion day, within the altitudinal range of 70–80 km, align with those reported by Sivakumar
 209 et al. (2001). They identified inversion day temperature variability in the altitudinal range of 73–
 210 79 km. Additionally, Sivakandan et al. (2014) examined mesospheric inversions in the 60–105 km
 211 altitude range over low-latitude regions. Their findings closely match our results.

212
 213 **Figure 4.** The frequency occurrence rate (percentage) of the (a) upper and (b) lower inversion
 214 temperatures during 2005-2020 over low latitudes.

215 Figure 4 shows the frequency occurrence rate (%) of mesospheric inversion layers (MILs) in
 216 histograms. Figure 4(a) shows the occurrence rate for upper MILs, while Figure 4(b) shows the
 217 rate for lower MILs. The mean frequency occurrence rate of upper inversions is approximately
 218 below 40%. Peak rates range from 60% to 78%, notably in the years 2008, 2010, and mid-2016.
 219 In contrast, the mean occurrence rate for lower inversions is below 20%. Overall, the occurrence
 220 rate for upper inversions is relatively higher compared to lower inversions. This may be related to
 221 atmospheric wave activities, mainly gravity waves. Hauchecorne et al. (1987) and France et al.
 222 (2015) discuss the effects of gravity waves on inversion variability in the upper and lower
 223 mesosphere. Based on these findings, Figure 5 examines the characteristics of inversion layers,
 224 including their amplitude and thickness. Figure 5 illustrates the characteristics of mesospheric
 225 temperature variability on an inversion day. It focuses on base height, amplitude, and thickness,
 226 before examining the effects of gravity waves on an inversion. Histograms show the frequency of
 227 amplitude, thickness, and base height for inversion day MLT temperature variability. These
 228 histograms feature best-fit Gaussian distribution curves, represented by red lines. The observed
 229 distributions align with Gaussian curves, indicating that the number of mesospheric inversion
 230 layers (MILs) follows a normal distribution. This suggests that the attributes are real-valued
 231 random variables. The left column has three rows showing histograms of (a) amplitude, (b)
 232 thickness, and (c) base height of the inversion day temperature variability for the upper MLT.
 233 These histograms also include their statistical values, mean, and standard deviations (SD). The
 234 corresponding right column has three rows representing (d) amplitude, (e) thickness, and (f) base
 235 height of the inversion day temperature variability for the lower MLT region.

236

237 **Figure 5.** The histograms depict the occurrence of MLT inversion day temperature variability. The
 238 first vertical panel shows the distribution of (a) amplitude, (b) thickness, and (c) base height for
 239 the upper inversion day. The second vertical panel presents the corresponding distribution for the
 240 lower inversion, including (d) amplitude, (e) thickness, and (f) base height.

241 The amplitude of upper inversion day temperature variability in Figure 5(a) ranges between 20
 242 and 80 K, with a peak value of 38 K. This follows a Gaussian distribution with a large standard
 243 deviation (SD) of 18.6. The thickness of the inversion layer for upper MILs, shown in Figure 5(b),
 244 ranges from 3 to 9 K. The most probable value is 5.5 K, with a low SD of 2.3. The base height of
 245 the upper MIL in Figure 5(c) spans from ~80 to 90 km, with a peak value of around 83 km. This
 246 indicates a large number of upper MLT inversions, with an SD of 2.13. The highest number of
 247 upper inversions between 2005 and 2020 is observed at 82 km. This may be attributed to gravity
 248 wave breaking and energy dissipation, influenced by waves generated from lower atmospheric
 249 regions and solar flux impacts. The lower inversion amplitude, depicted in Figure 5(d), ranges
 250 between 10 and 60 K, with a peak value of 25 K and a standard deviation (SD) of 14.5. The
 251 thickness of the lower inversion, shown in Figure 5(e), ranges from 3 to 8 km, with the most
 252 probable value at 3.8 km and a low SD of 1.72. The base height of the lower inversion in Figure
 253 5(f) ranges from 70 to 80 km, with a peak value of around 74 km and a lower SD of 1.93. Previous
 254 investigations by Sivakandan et al. (2014) from the Indian sector reported amplitudes ranging from
 255 14–39 K in 2002 and 15–42 K in 2008. The thicknesses ranged between 2.7–7.5 km in 2002 and

256 2.8–7.3 km in 2008, under the influence of solar flux. These findings align well with the present
257 study, indicating no significant variation in characterizing mesospheric inversion based on
258 amplitude and thickness in the low-latitude region within the altitude range of 60 to 90 km.

259 3.2 Latitudinal Variations of Mesospheric Inversion Layers (MILs)

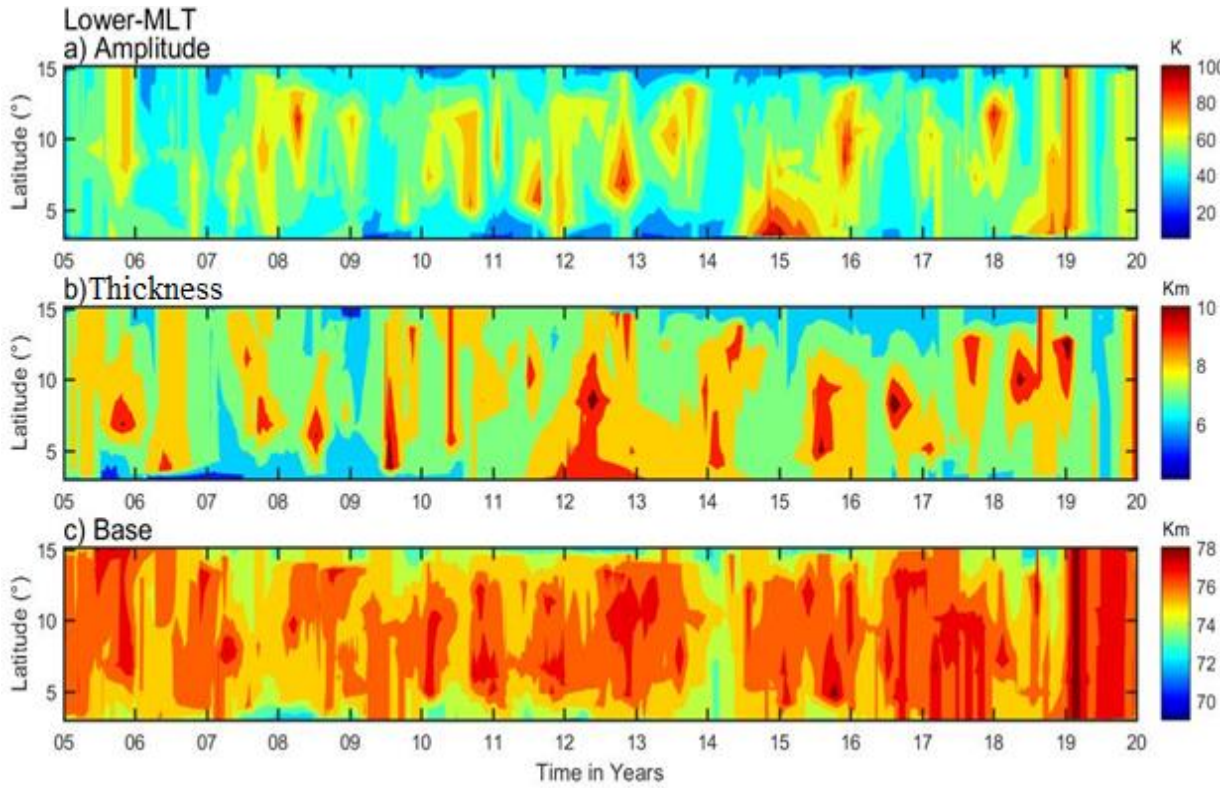

260 This section examines the spatiotemporal (latitudinal-time) variability of upper and lower
261 mesosphere inversion phenomena. Contour plots of time vs. latitude in Figures 6 and 7,
262 respectively, characterize this variability based on amplitude, thickness, and base height over the
263 low-latitude band ($3\text{--}15^\circ$) during 2005–2020. The Upper MILs phenomenon is observed around
264 80–90 km. The maximum amplitude, in the range of 90–120 K, occurs over latitude bands ($5\text{--}12^\circ$)
265 during 2005, 2007, mid-2011, 2013, 2015, 2016, mid-2019, and 2020 (Figure 6(a)). The second
266 horizontal panel in Figure 6(b) shows the inversion thickness, with a maximum range of $\sim(8\text{--}12$
267 km) across the entire latitudinal region ($3\text{--}15^\circ$ N). Figure 6(c) shows the relative maximum
268 inversion base height, around $\sim(84\text{--}88$ km), in the latitudinal range between 4° and 14° N during
269 2006, 2008, 2010, 2012, 2016, and 2018.

270 **Figure 6.** The daily upper inversions ($\sim 80\text{--}90$ km) of (a) amplitude, (b) thickness, and (c) base
271 height during 2005-2020 over latitudinal variation.
272

273 Contour plots in Figure 7(a, b, and c) show the latitudinal variations of the lower inversion (MILs)
274 phenomenon, based on amplitude, thickness, and base height, respectively. These plots cover an
275 altitudinal range of $\sim 70\text{--}80$ km. The lower inversion amplitude generally ranges from $\sim 30\text{--}60$ k

276 across all latitudinal bands. However, it reaches a maximum range of $\sim(80-100 \text{ k})$ during 2013,
 277 2015, 2016, and 2019 in various latitudinal regions between 5 and 140 N. Figure 7(b) shows an
 278 inversion thickness of 5-7 km across the entire latitude band, except for a maximum thickness of
 279 8-10 km. Figure 7(c) shows a base height of 76-80 km for most latitudes and periods. However,
 280 there are exceptions: 2008, 2014, and mid-year 2018 exhibit a maximum base height.

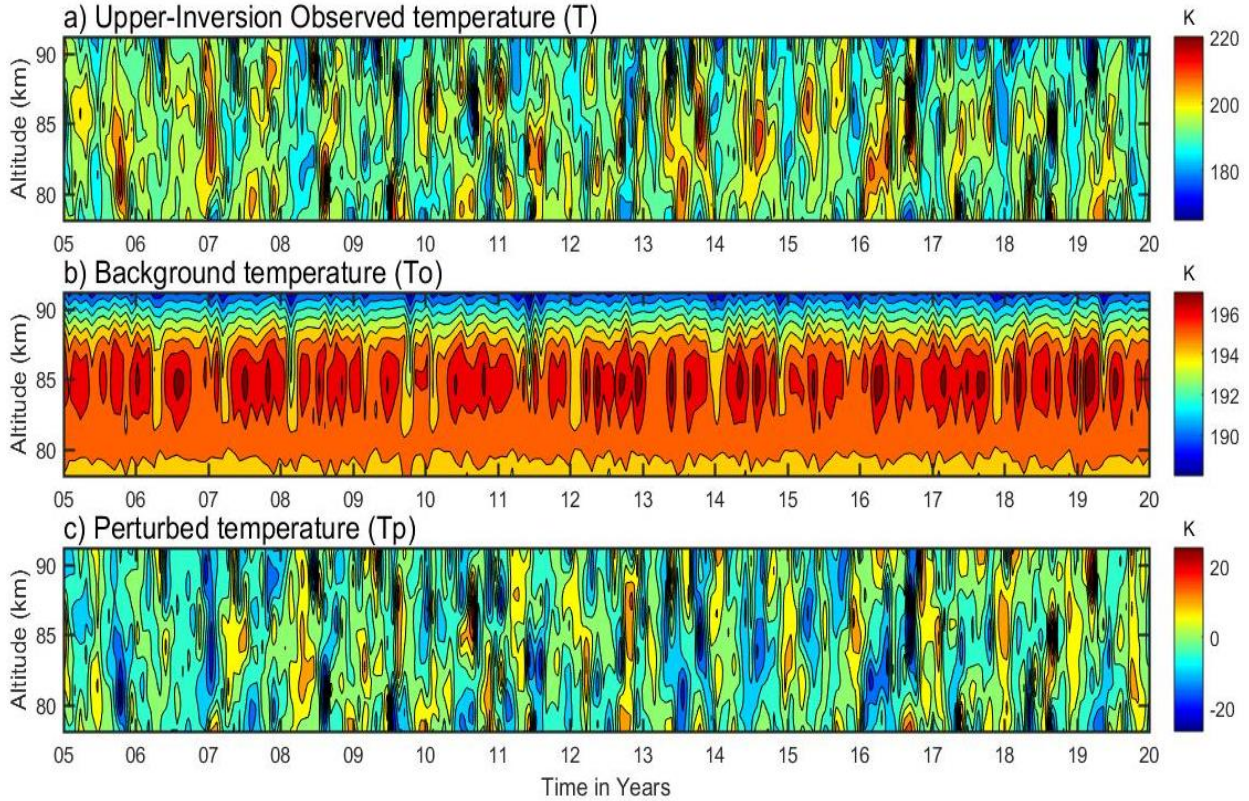

281
 282 **Figure 7.** Same as Figure 5, but for the lower mesosphere inversions ($\sim 70-80 \text{ km}$).
 283 Figures 6 and 7 demonstrate that the upper inversion exhibits higher amplitude and thickness
 284 compared to the lower inversion, suggesting a highly dynamic phenomenon in the upper
 285 mesosphere region. Satellite measurements, particularly those from TIMED/SABER, provide
 286 valuable insights into latitudinal variations in MILs. These observations confirm that MILs also
 287 occur at low latitudes (Gan et al., 2012).

288 **3.3 Separations of the Perturbed Temperature in the Mesosphere Region**

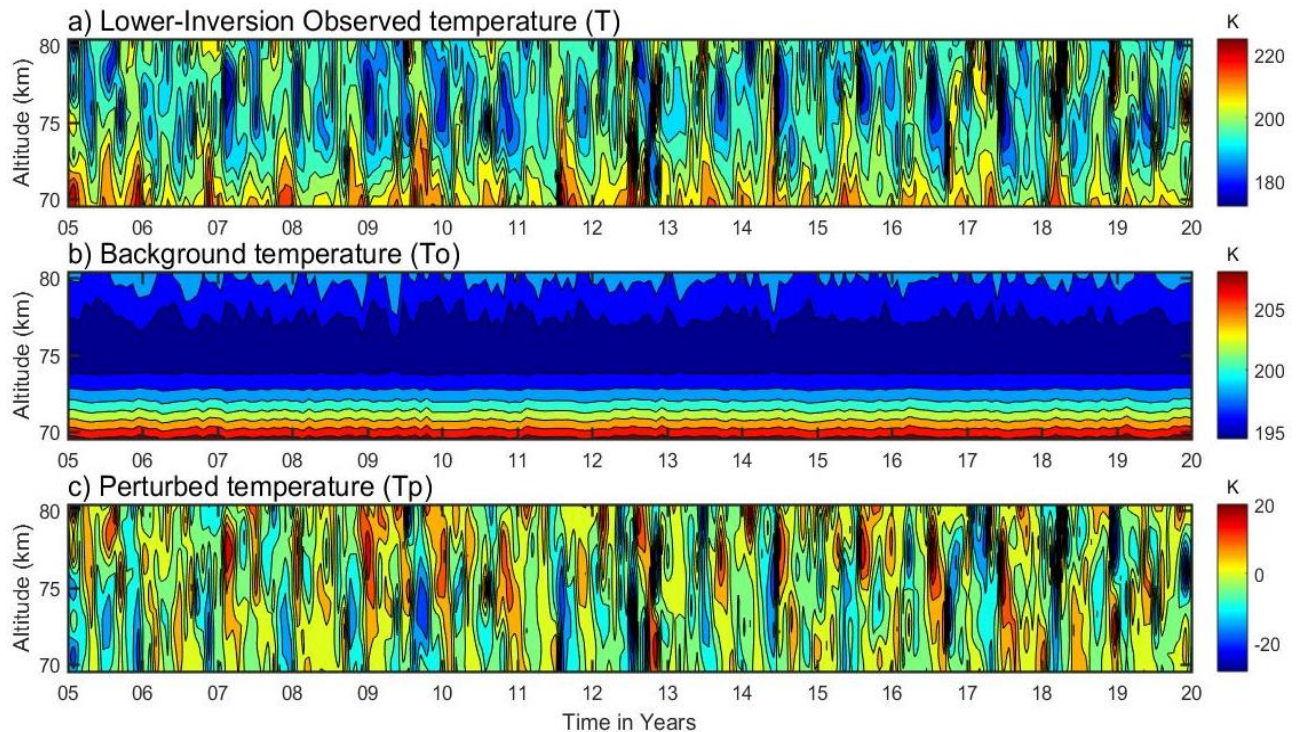

289 The perturbed temperature (T_p) of the upper and lower MLT inversions during the period of 2005-
 290 2020 can further be used to calculate their derived potential energy of gravity waves and the Brunt-
 291 Väisälä frequencies (N^2). First, the upper-temperature inversion profiles are identified in the MLT
 292 region during the entire observational period of 2005-2020, as displayed in the contour plot of
 293 Figure 8(a). The observed temperature ranges from $\sim 170-220 \text{ K}$ with minimal variability. A 3rd-
 294 order polynomial fit is applied to calculate the background temperature (T_0), as shown in the

295 contour plot of Figure 8(b). This background temperature exhibits periodic variability over an
 296 altitude of around ~82-87 km, ranging from ~195-197 K. The perturbed temperature profiles (T_p),
 297 calculated as the difference between the observed inversion temperature (T) and the corresponding
 298 background temperature profiles (T_o), range from -25 to +25 K, as shown in Figure 8(c).

299 **Figure 8.** The upper mesosphere temperatures in the vertical panel are: (a) inversion day observed
 300 temperature; (b) background temperature; and (c) perturbed temperature in the upper mesosphere
 301 region.
 302

303 A similar procedure is used to calculate the perturbed temperature (T_p), observed temperature, and
 304 background temperature in the lower mesosphere region from 2005 to 2020. Their corresponding
 305 contours are displayed in Figure 9(a-c). In Figure 9(a), the observed temperature of the lower
 306 inversion ranges from ~170-220 K. The background temperature of the lower inversion ranges
 307 from ~ 195-210 K, with maximum values of ~200-210 K at a height of ~70-72 Km, as shown in
 308 Figure 9(b). The perturbed temperature in Figure 9(c) ranges from -25 to 20 K. Notably, the upper
 309 mesosphere perturbed temperature is at its maximum compared to the lower mesosphere region,
 310 possibly due to a highly dynamic phenomenon.

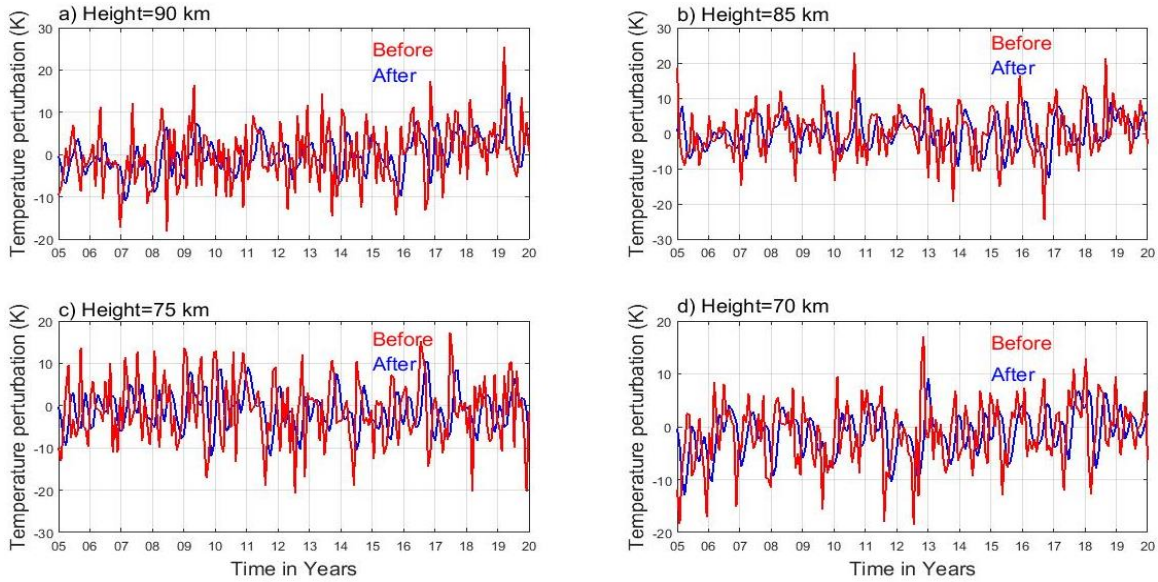

311
312 **Figure 9.** Same as Figure 7, but for the lower mesosphere atmospheric region.

313 **3.4 Effects of Gravity Waves on Mesosphere Inversions and Associated Instability**

314 Gravity waves occur when air parcels oscillate due to the restoring force of gravity after being
 315 displaced vertically. These waves are generated by various processes, including airflow over
 316 mountains, convection, and wind shear. Gravity waves and mesospheric inversion layers (MILs)
 317 are interconnected phenomena, particularly in the mesosphere. MILs are layers within the
 318 mesosphere where the temperature profile shows an inversion, meaning the temperature increases
 319 with altitude, unlike the typical decrease. These inversion layers often form due to dynamic
 320 processes, such as the breaking and dissipation of gravity waves. When vertically propagating
 321 waves break and dissipate, they transfer their energy and momentum into the atmosphere. This
 322 significantly affects the thermal structure, particularly increasing mesospheric temperature
 323 variability with elevation, a phenomenon known as the inversion (see Figure 11). Studies by
 324 Holton et al. (2003) and Holton and Hakim (2013) have demonstrated the connection between the
 325 potential energy of gravity waves and inversions.

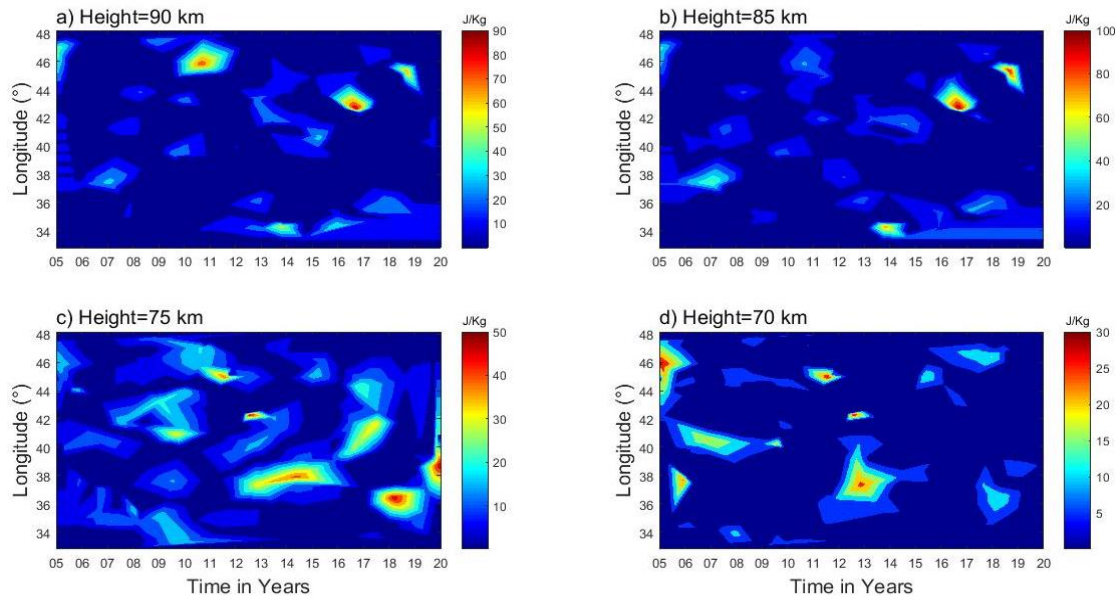

326 This section explores the longitudinal variability of gravity waves' contribution to mesospheric
 327 inversion layers (MILs). The investigation involves calculating potential energy and assessing
 328 instability using the Brunt-Väisälä frequency (N^2) derived from perturbed temperatures. A high-
 329 pass band filter with a one-hour interval cut-off frequency is applied to the perturbed temperature

330 (T_p) data before deriving the waves' potential energy. This process covers the period from 2005 to
 331 2020 at selected heights of 90, 85, 75, and 70 km (see Figure 10 a-d). The high-pass band filter
 332 eliminates the influence of long-period oscillations, such as tidal or planetary waves, on the
 333 inversion, isolating the gravity waves (Gw). The effects of the high-pass band filter are visible in
 334 Figure 10 (a-d), showing the upper mesosphere at 90 and 85 km and the lower mesosphere at 75
 335 and 70 km. The filter reduces the amplitude of the perturbed temperature in the upper mesosphere
 336 (90 and 85 km) from approximately $\sim(-20$ to 20 K) to $\sim(-10$ to 10 K). It also reduces the amplitude
 337 in the lower mesosphere from $\sim(-20$ to 20 K) to $\sim(-8$ to 8 K) by eliminating higher amplitudes.

338
 339 **Figure 10.** Perturbed temperature profiles before (red color) and after (blue color) applying the
 340 low-pass band filter for the upper (85 and 90 km) and lower (70 and 75 km) regions.

341 Potential energy (E_p) is constructed using the time series filtered perturbed temperature (T_p') at
 342 selected heights of 90, 85, 75, and 70 km. This approach is based on the fact that gravity wave
 343 activity is represented by potential energy, as described by numerous authors (Tsuda et al., 2000;
 344 Wang and Geller, 2003; Liu et al., 2014; Thurairajah et al., 2014). Figure 11 (a-d) demonstrates
 345 the spatiotemporal variability of gravity wave potential energy, showing the upper mesosphere
 346 region at 90 and 85 km and the lower mesosphere region at 75 and 70 km.

347

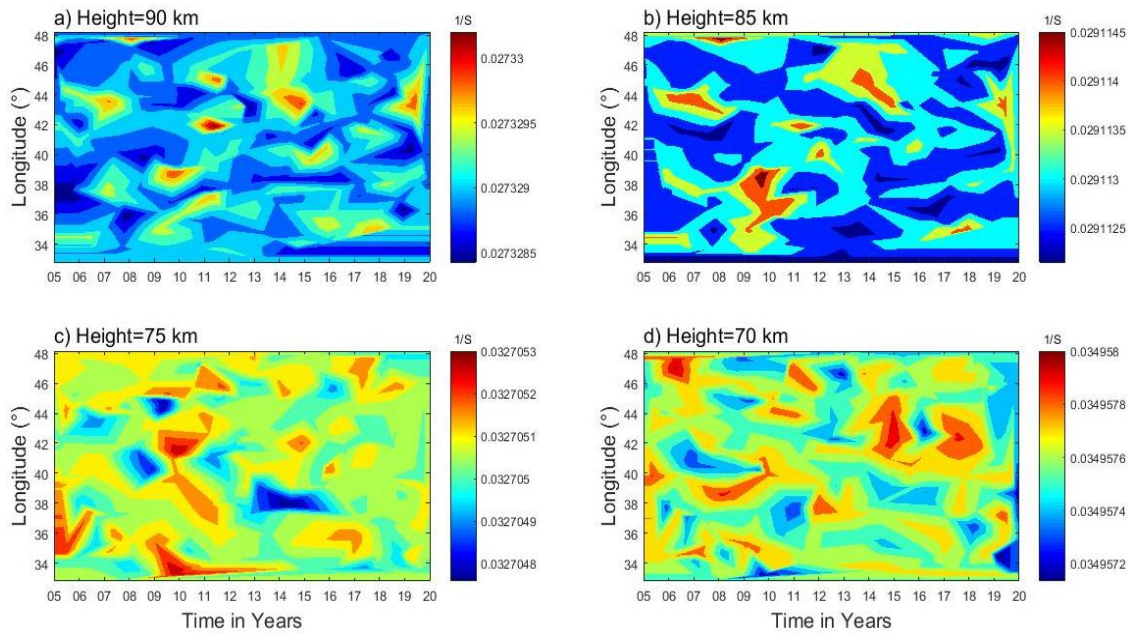

348 **Figure 11.** Gravity wave potential energy for the upper (85 and 90 km) and lower (70 and 75
 349 km) mesosphere regions.

350 Figure 11(a) shows maximum gravity wave potential energies, ranging from ~70 to 90 J/kg, over
 351 the longitudinal regions of 45-47° E, 43° E, and 44° E during 2011, 2017, and 2019 for upper
 352 mesosphere inversions at 90 km. In contrast, potential energies around ~10 to 60 J/kg are present
 353 across the entire longitudinal region from 33-48° E. Figure 11(b) shows maximum potential
 354 energies of ~70 to 100 J/kg over the longitudinal regions of 34°, 44°, and 46° E during 2014, 2016,
 355 and 2018 at 85 km. Minimum potential energies between 20 and 70 J/kg appear over the longitude
 356 regions from 33-48° E. Figures 11(c) and 11(d) depict the gravity wave potential energy in the
 357 lower MLT regions at 75 and 70 km, respectively. At 75 km, Figure 11(c) shows a relative
 358 maximum potential energy of 40-50 J/kg over the longitudinal regions of 46°, 42°, 40°, 37°, 36°,
 359 and 38° E during 2011, 2012, 2017, 2013–2015, 2018, and 2020. Similarly, Figure 11(d) illustrates
 360 gravity wave potential energy ranging from 2-30 J/kg at 70 km across the longitudinal region of
 361 33-48° E. Maximum potential energy of 25-30 J/kg is observed in certain longitudinal regions over
 362 time.

363 Gravity wave breaking in the upper atmosphere usually leads to more turbulence and mixing. As
 364 gravity waves rise and break, they transform their potential and kinetic energy into turbulent
 365 energy. This process increases vertical mixing and transports momentum. This energy transfer can
 366 change thermal patterns and affect the overall dynamics of the upper atmosphere. Interestingly,
 367 the dissipation of gravity waves can lead to localized warming or the formation of mesospheric

368 inversion layers (MILs). This is especially important in the upper mesosphere and lower
 369 thermosphere, where wave breaking can significantly impact the thermal structure. Gravity wave
 370 propagation and dissipation are major forces in the MLT region (Lindzen, 1981; Holton, 1983),
 371 influencing middle and upper atmospheric inversion. In a nutshell, gravity wave breaking and the
 372 dissipation of energy and momentum are key players in both the upper and lower atmospheres,
 373 affecting turbulence, circulation patterns, temperature, density, and weather systems.

374 Gravity waves come in different sizes, with smaller waves being the main drivers of instability
 375 and turbulence in the MLT (mesosphere and lower thermosphere) region (Liu and Meriwether,
 376 2004; Szewczyk et al., 2013). Hauchecorne et al. (1987) proposed a model where a series of
 377 breaking gravity waves leads to the formation of MILs through the gradual accumulation of heat,
 378 which contributes to instability. Understanding mesospheric inversion layer (MIL) phenomena is
 379 crucial for understanding MLT atmospheric dynamics, especially when it comes to stability and
 380 energy transfer. To investigate the role of gravity waves in MLT instability, the Brunt-Väisälä
 381 frequency was used. Contour plots in Figure 12 (a-d) show the spatiotemporal variability of the
 382 Brunt-Väisälä frequency, with Figures 12(a and b) representing the upper mesosphere (90 and 85
 383 km) and Figures 12(c and d) representing the lower mesosphere (75 and 70 km). The Brunt-Väisälä
 384 frequency (N^2) shows that the upper MLT region is more unstable (~ 0.027 at 90 km and ~ 0.029 at
 385 85 km) than the lower mesosphere (~ 0.033 at 75 km and ~ 0.035 at 70 km).

386
 387 Figure 12. Brunt-Vaisala frequency (N^2) profiles for the upper (85 and 90 km) and lower (70 and
 388 75 km) mesosphere regions.

389 4. Summary

390 In this article, 16 years of SABER MLT temperature profiles are utilized to investigate the MIL
391 phenomenon and its causative mechanism through gravity wave potential energy (P_E) and
392 instability criteria of Brunt-Väisälä frequency (N^2) over low latitude bands. The following
393 conclusions are drawn from the observations in this article:

- 394 ✓ The upper mesosphere inversion frequency occurs more often than the lower mesosphere
395 inversion.
- 396 ✓ Analysis of the MIL characteristic features reveals the most probable values for the upper
397 inversion: amplitude of 38 k, thickness of 5.5 km, and base height of 78 km. The lower
398 inversion has an amplitude of 25 K, a thickness of 3.8 km, and a base height of 73 km.
- 399 ✓ The upper mesosphere region has higher gravity wave potential energy compared to the lower
400 mesosphere region.
- 401 ✓ The high potential energy in the upper mesosphere region is likely due to the deposition of
402 energy and momentum by gravity wave breaking. This could influence the dynamics of the
403 inversion phenomenon.
- 404 ✓ The Brunt-Väisälä frequency (N^2) indicates that the upper mesosphere region is less stable than
405 the lower mesosphere region. This lower stability contributes to the high potential energy in
406 the upper mesosphere, which leads to larger inversion phenomena.
- 407 ✓ Atmospheric processes vary significantly from region to region, with altitude, and over time.
