Abstract. The ground-level atmospheric potential gradient (PG) has been measured with a radioactive collector method in Stanisław Kalinowski Geophysical Observatory in Świder (52.12°N, 21.23°E), Poland, for several decades. Long-term measurements analysed previously revealed rather typical behaviour in the diurnal and seasonal variations of the PG of a land station controlled by pollution. Observation of the potential gradient at such a station usually show a maximum at local winter months which are mostly affected by anthropogenic pollution. The 1965–2005 series has been newly analysed to describe the Świder PG variations in greater detail, also in connection with an analysis of simultaneous measurements of condensation nuclei measured at 6, 12, 18 UT. An attempt is made to calculate the diurnal and seasonal variations at condensation nuclei number concentrations below 10000 cm⁻³. There is a decrease of the PG in the diurnal variation by up to 11 % in the winter, and no significant change in the summer. The reduction in the annual variation is 11-26 % with the biggest difference in February. In the summer months, this difference is negligible. Such differences can be predicted with a simplified model of electrical conductivity including the aerosol composition of water soluble and soot particles, the main components of continental aerosol. With this model we obtained changes in the conductivity and the PG in up to 30 % in the winter, and 6 % in the summer. Despite the efforts to minimise the aerosol effect on the PG, the character of the PG seasonal and annual variation preserves its character with a maximum in the Northern Hemisphere winter and the minimum in the summer.

1 Introduction

1.1 Diurnal and seasonal variation of GEC as deduced from the atmospheric electricity stations observations

The Global Atmospheric Electric Circuit (GEC) manifests itself in the atmospheric potential gradient (PG) observed at any location on the globe (Rycroft et al., 2000). Diurnal and seasonal variations of the PG are the earliest recognised changes of the PG (e.g., Witkowski, 1902; Israël, 1973a, b). It has been also early established that even in fair weather (FW) conditions the curves of the diurnal variation had different shapes depending on the location of stations, season and local conditions. At land stations a double oscillation was often observed in the PG variation, present in at least one (usually warm) season (Israël, 1973a). For example, at Kew, Uppsala, Tokyo the diurnal variation of the PG exhibits the double oscillations at any time of

the year while at Helsinki, Tortosa or Vassijaure it had the double oscillation only in the local summer. At polar stations and over the oceans a single oscillation is usually observed throughout the year and its character is unitary in Universal Time (UT) (Odzimek, 2019) which has been firstly recognised by Hoffmann (1924). The average fair weather variation of the PG calculated from 1920–1925 observations over the oceans on board of the Carnegie Institution of Washington research vessel “Carnegie” is known as the Carnegie curve (Parkinson and Torreson, 1931; Harrison, 2013). This curve is considered to reflect the variation of the diurnal activity of the global circuit and is often compared with the diurnal variation of the PG observed in fair weather conditions from other places on the globe (e.g., Kubicki et al., 2016; Nicoll et al., 2019; Tacza et al., 2020; Michnowski et al., 2021, and others). In the seasonal or annual variation many observations indicated a winter maximum in the atmospheric potential gradient compared to the summer. Adlerman and Williams (1996) investigated the connection between the PG local winter maximum and more intensive anthropogenic emission of Aitken nuclei which occurred independent of the station’s location in Northern or Southern Hemispheres. The annual variation of the air conductivity which minimises during the local winter as compared to the summer supported this relationship.

A question arises then when the true maximum of the GEC is, and Adlerman and Williams (1996) argued this should be investigated based on observations in locations relatively free from aerosol particles effects. Their analysis of Mauna Loa air-Earth current data and reanalysis of Carnegie and Maud cruises PG data indicated a GEC maximum in the Northern hemisphere summer, in agreement with the maximum of global thunderstorm activity (Christian et al., 2003).

In this paper we reanalyse the diurnal, seasonal and annual variation in the atmospheric potential gradient at the land station Świder (Poland) which also has condensation nuclei monitoring. Previous analyses of the diurnal variation of the PG indicate that Świder is characterised by the double oscillation prevalent in the summer (Northern Hemisphere summer), and the single oscillation in the winter. Furthermore PG values in winter are of higher average amplitude, explained by the higher emissions of anthropogenic aerosols affecting the local electric conductivity (Warzecha, 1976; Kubicki et al., 2003, 2007; Michnowski et al., 2021). This is rather a typical behaviour of the PG at a rural land station (Israël, 1973a). Here we analyse the variations at possible low levels of the nuclei number concentration, i.e. less than 10000 particles in cubic centimetre, to investigate whether, with such a limit applied, this may have any considerable effect on the seasonal peaks of the PG. We choose concentrations below 10000 particles per cm^{-3} because these are characteristic for rural, non-urban and remote regions of the globe (e.g., Mohnen and Hidy, 2010).

2 Świder published data set of atmospheric electricity

Stanisław Kalinowski Geophysical Observatory of the Institute of Geophysics, Polish Academy of Sciences, is located 25 km south-west of Warsaw near the Otwock town in the central Poland (52.12°N, 21.23°E). It was founded as a Magnetic Observatory, and since 1929 also worked as an atmospheric electricity station except during the World War II. The pre-war electric measurements were lost, and publication of new results of resumed electric measurements started in 1958. Measurements reports from years 1957–2005 were subsequently published in the Observatory yearbooks (Warzecha, 1960, 1968; Kubicki, 2006). Since the beginning of the atmospheric electric measurements, the PG was the main variable to be measured. After 1949

the measurements were complemented by air conductivity recordings and in the 2000' by the Maxwell current density measurements. In this paper we analyse only PG data since it is the most commonly measured parameter of atmospheric electricity worldwide.

2.1 PG data

60 The measurements of fair weather atmospheric potential gradient (or the atmospheric electric field strength) at the Świder observatory have been made with radioactive collectors (the activity of about $30 \mu Ci$). Initially two independent collectors were used, each consisting of the radioactive sonde at a height of about 2 m connected to an electrometer and a recording milliammeter. At the beginning Benndorf electrometers were used, in 1964 replaced by an observatory-built electrometer (Warzecha, 1968, 1976). After 2000 it was replaced by commercially available electrometers. The recording milliammeter was
65 also later replaced by an A/D logger. The PG measurements have absolute calibration and reduction to free plane value (e.g., Kubicki, 2006, and earlier yearbooks). The hourly averages of the PG measured with the collector as well as the positive air conductivity data were published in the observatory yearbooks for the period 1957–2005. The list of all yearbooks used in this study can be found in Appendix A.

2.2 Condensation nuclei data

70 Since the continuous atmospheric electricity observations simultaneous systematic measurements of aerosol particle number concentrations of the condensation nuclei type (CN, particle size from $0.005 \mu m$ to $10 \mu m$) were made (Warzecha, 1960, 1974). The measurements have been made at a height of 1 m, three times a day at about 6, 12 and 18 UT. From 1957 to 1981 a small Scholz counter has been used for this purpose and since 1982 an observatory-built photoelectric counter (Kubicki et al., 2003). Only during 1998–1999 the measurements have been taken at 3 m height. The measurements of the concentration of
75 condensation nuclei at the three terms have been included in the observatory yearbooks.

2.3 Criteria of fair weather conditions

In order to investigate global signal of atmospheric electricity and minimise the effects of local weather, criteria for fair weather conditions are used (Imyanitov and Chubarina, 1967). Since 1965 a WMO standard for the fair-weather conditions has been applied at Świder: low cloudiness up to 3/8 in okta scale, no precipitation or fog, wind speed less than 6 m/s and PG amplitude
80 less than 1000 V/m (e.g., Warzecha, 1968; Kubicki, 2006).

3 Overview of fair-weather PG and CN data

In our analysis we consider all fair weather (FW) hourly values of the potential gradient (PG) and the condensation nuclei concentrations (CN) from 6, 12, 18 UT published in the Observatory yearbooks 1965–2005. There is a total number of the hourly PG values of 131634 with a subset of 16072 hourly values with corresponding CN concentrations and 3303 missing
85 data (2.5 %). Table B1 and Table B2 in the Appendix B include the number of FW hourly average mean values of PG and

number of FW days (24 h) for each month and year of the analysed period. There are more FW values during the local warmer seasons from March to September. The percentage of FW hours is about 37 % on average (see also Table 1) and varies between 49 % in the summer and 23 % during winter. The total number of FW days is equal to 1414. The percentage of FW days is about 9 % on average and rises to 14 % during summer and decreases to 4 % during winter.

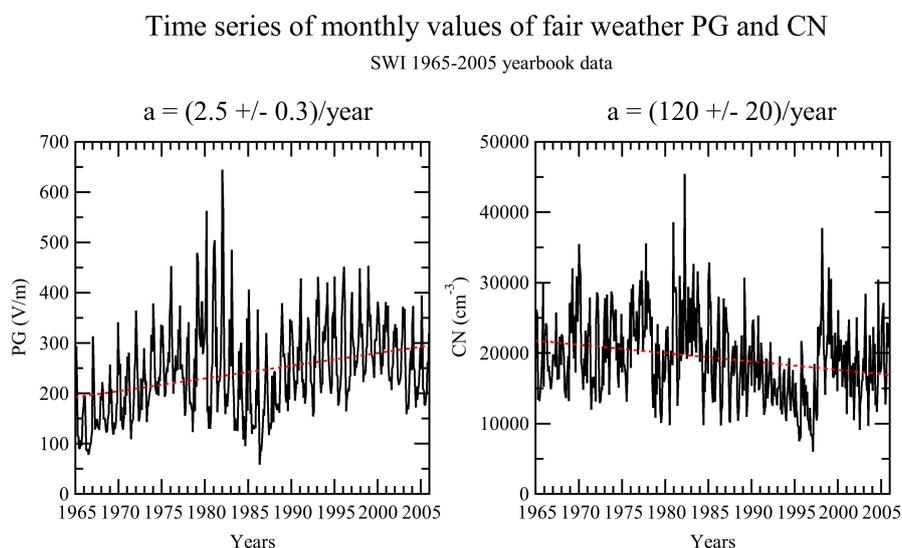

Figure 1. Time series of monthly averaged values of fair-weather PG and CN values over January 1965 – December 2005. The dashed red lines indicate positive trend for PG (2.5 ± 0.3 V/m per year) and negative trend for CN (-120 ± 20 cm⁻³).

90 The time variations of monthly mean values of PG and CN during this period is shown in Fig. 1. There seems to be several periods of monotonic increase and decrease of the PG, and a general trend of increase of the PG by 2.5 V/m per year. The general trend for CN concentration is a decrease by -120 ± 20 cm⁻³ per year. Analysis of the long-term variation in these series will be a subject of another study.

Histogram of these values and main statistical parameters of the set are given in Fig. 2. The mean average, Ma, of the total
95 fair-weather PG of 1965–2005 is 230 V/m, and the standard deviation, SD, is 131 V/m. The median, Me, is 207 V/m, the first quartile, Q1, equals 139 V/m, and the third quartile, Q3, 294 V/m. The kurtosis, K, is equal to 5.4 and the skewness, S, is 1.3 what characterises a leptokurtic and right-skewed distribution. These parameters describe the total FW PG set but in next sections we concentrate on the subset of PG hours for which simultaneously measured CN data also exist, and particularly on the subset for limited CN concentrations up to 10000 cm⁻³. The statistical parameters of the distribution of these subsets are
100 also given in Fig. 2 separated by slashes. The selection of PG data measured at the same time as CN creates a new distribution with slightly higher mean (248 V/m) or median value (224 V/m) but similar kurtosis and skewness of ~ 5 and ~ 1 , respectively. When we further limit the CN concentration the mean and median value are lower, 221 V/m and 208 V/m, respectively.

Selection of PG-CN pairs limits the number of values, N, to 16072 (12 %) and with the condition of CN lower than 10000 cm^{-3} the number of pairs decreases to 3593 (3 %) as indicated in the Table 1.

Table 1. Number of total hours for the period January 1965 – December 2005 together with number of all fair-weather PG hours and number of fair-weather PG hours corresponding to the CN concentration values below 10000 cm^{-3} , 8000 cm^{-3} , 6000 cm^{-3} and 4000 cm^{-3} , respectively. The percentages refer to the number in bold in the same colour in the first row of the table.

All hours 1965-2005	All FW hours 1965-2005	FW PG hours 1965-2005	FW PG all CN	FW PG CN<10000	FW PG CN<8000	FW PG CN<6000	FW PG CN<4000
359400	134937	131634	16072	3593	2025	915	122
	37.54 %	97.5 %	4.47 %	1.00 %	0.56 %	0.25 %	0.03 %
			11.91 %	2.66 %	1.50 %	0.69 %	0.09 %
			12.21 %	2.72 %	1.54 %	0.71 %	0.09 %
				22.35 %	12.60 %	5.69 %	0.76 %

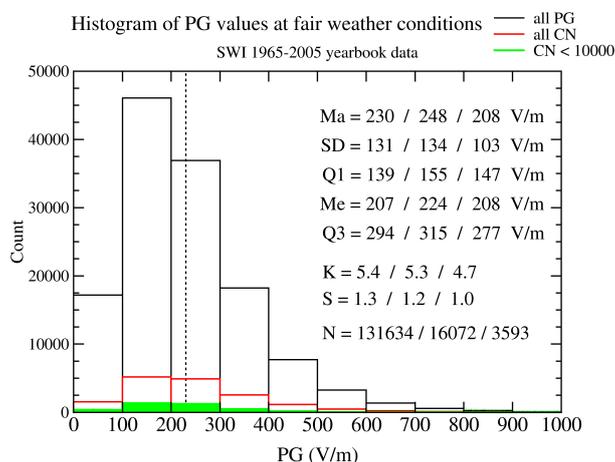

Figure 2. Histogram of the PG values measured during fair-weather conditions in January 1965 – December 2005: black colour – all PG values, red colour – PG values recorded simultaneously with CN concentrations, green colour – the PG values at CN concentrations below 10000 cm^{-3} . The black dashed line represents mean PG value (230 V/m). The other statistical parameters separately for the three PG groups are given in the legend, including the number of data values, N.

105 In Fig. 3 we show the histogram of the measured CN values. The mean value of the total fair-weather CN concentration is 18980 cm^{-3} and the standard deviation is 13240 cm^{-3} . The median is 15510 cm^{-3} , the first quartile is 10340 cm^{-3} and the third quartile is 22650 cm^{-3} . The kurtosis is equal to 8.8 and the skewness 2.1 what indicates a leptokurtic and right-skewed distribution. The number of fair-weather CN values is 16756 and the subset of CN below 10000 cm^{-3} (see green frame in

Fig. 3) is 3736 which corresponds to 22 % of the total CN values. Table 2 and Fig. 4 show the main statistical measures of the
 110 FW PG and CN distributions discussed above and separately for each season. Fig. 4 presents the seasonal distribution of CN
 concentrations. The green line separates the distributions of CN concentrations below 10000 cm^{-3} which will be used in next
 sections.

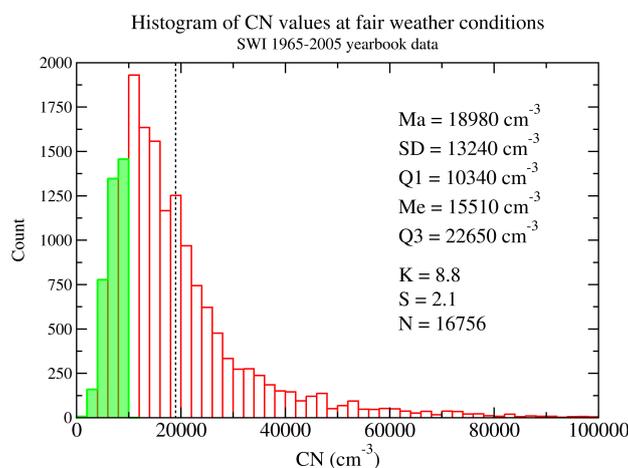

Figure 3. Histogram of hourly averaged CN concentrations at fair-weather conditions in January 1965 – December 2005: CN below 10000 cm^{-3} are framed in green, red colour – all CN. The black dashed line represents mean CN concentration value of 18980 cm^{-3} .

Table 2. Statistical measures of the distribution of all values FW PG and CN in the series 1965-2005.

	Spring		Summer		Autumn		Winter		all year	
	PG (V/m)	CN (cm^{-3})								
mean	250	21180	193	15330	253	20020	351	20930	249	18970
sd	129	14940	84	11220	130	12970	165	12800	134	13270
skewness	1.2	1.9	0.8	2.9	1.0	1.9	0.6	1.7	1.2	2.1
kurtosis	5.7	7.0	4.8	15.2	4.7	7.9	3.2	7.4	5.3	8.8

The lowest concentrations of CN in fair weather conditions (there is almost twice more counts of the concentrations in the
 summer compared to winter) are observed in the summer with the mean value of $\sim 15000 \text{ cm}^{-3}$. In the other seasons the mean
 115 value is close to 20000 cm^{-3} with the highest standard deviation values in the spring $\sim 15000 \text{ cm}^{-3}$ and the lowest ~ 11000
 cm^{-3} in the summer and $\sim 13000 \text{ cm}^{-3}$ in the winter and in the autumn. In terms of kurtosis and skewness the values in the
 spring, autumn and winter are similar and vary between 7.0-7.9 and 1.7-1.9, respectively. In the summer these parameters are
 higher reaching values 15.2 and 2.9, respectively.

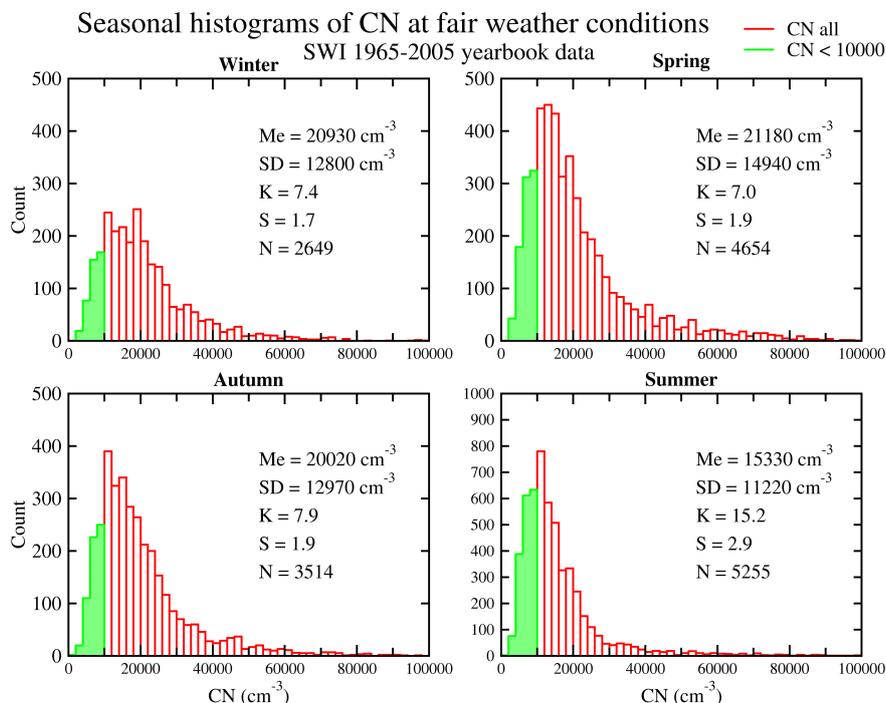

Figure 4. Seasonal histograms of the hourly averaged (6, 12, 18 UT) CN concentration values measured during fair weather conditions for the period January 1965 – December 2005: red colour – all CN concentration values, green colour – CN concentration values below 10000 cm⁻³. Note that Y-axis ranges for summer (0-1000 counts) is twice compared with the other seasons (0-500 counts).

4 Diurnal and seasonal variation of the potential gradient in Świder, 1965-2005

120 In this section we analyse the diurnal and seasonal variation of Świder FW PG and how it relates to different levels of CN concentrations. Previous works on the analysis of diurnal and seasonal variations of PG focused only in FW days which considered 24 hours of FW, i.e., a FW day needed to accomplished FW for each hour between 0 and 23 UT concerned only of 24h fair weather days (Kubicki et al., 2016). This restriction limited the amount of available data. Michnowski et al. (2021) used FW PG values with at least 12 hours of fair weather conditions. In this work we increase the amount of data taking in

125 account every FW hourly value to calculate the diurnal and seasonal variation.

4.1 Diurnal variation

Fig. 5 presents the PG diurnal variation separated by seasons (winter – December, January, February, spring – March, April, May, summer – June, July, August, autumn – September, October, November) and all year mean. The shape of the PG curve is substantially different depending on the season. During the winter months there is a single broad maximum lasting from the noon (~13 UT) until late evening (~20 UT) whereas during the spring-summer-autumn period double maxima (~7 and ~19 UT) are present. The amplitude variation of the PG curve during the winter is larger than in the summer (Table 2). Świder

130

is thus characterised by the type I of the “double oscillation” variation in the diurnal average curve as according to Israëi (1973a), i.e. the double oscillation is prevalent except of local wintertime and its maxima occur at different hours depending on the season. Differences between the PG diurnal curves, at Świder, and the classical Carnegie diurnal curve, the “single oscillation” and unitary variation in universal time – which is observed over the oceans and polar regions – come from the much greater variability and dynamics of the planetary boundary layer (PBL) characteristic for the location and at Świder affected by pollution, meteorological factors and seasonal effects (Kubicki et al., 2016; Nicoll et al., 2019; Michnowski et al., 2021, Section 4).

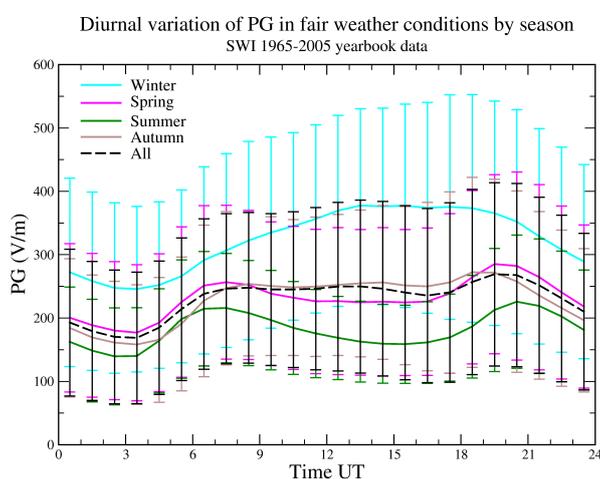

Figure 5. Diurnal variation of PG measured during fair-weather conditions by seasons and for the whole year in January 1965 – December 2005. The error bars represent ± 1 standard deviation.

Since we cannot calculate the whole diurnal variation of CN we show results only for 6, 12, 18 UT (represented by symbols) in Fig. 6. On the background (solid lines) is shown the Świder diurnal curves 1968/69 from Warzecha (1976), obtained from the recordings of the condensation nuclei concentrations using a Verzář counter every 15 minutes. We note that in this comparison we calculated the mean values only for 24-hour FW days since Warzecha presented the diurnal curves for cloudless days. The mean CN values for the seasons are given in the Table 2. The highest mean CN concentrations at these hours are registered at 12 UT although looking at diurnal curves of Warzecha (1976) this is already after the morning maximum of CN concentrations between 6 and 12 UT (all seasons) and before the afternoon/evening maximum. These values are especially high in winter and spring 1968/69. The values at 6 and 18 UT are similar, however the lowest values are noted in the morning. At 6 and 18 UT the mean CN concentrations in the spring and autumn are almost equal while at 12 UT the spring mean is higher, even than the winter value which generally is the highest among seasons. Compared with the diurnal curves of Warzecha (1976) the CN concentrations fairly agree with the diurnal variation except for the 18 UT (excluding summer) and for 12 UT in summer and autumn. Some differences are likely since we compare long-term mean values with one year means. Nevertheless, it is worth noting that the diurnal CN curves fall between the CN averages at one standard deviation.

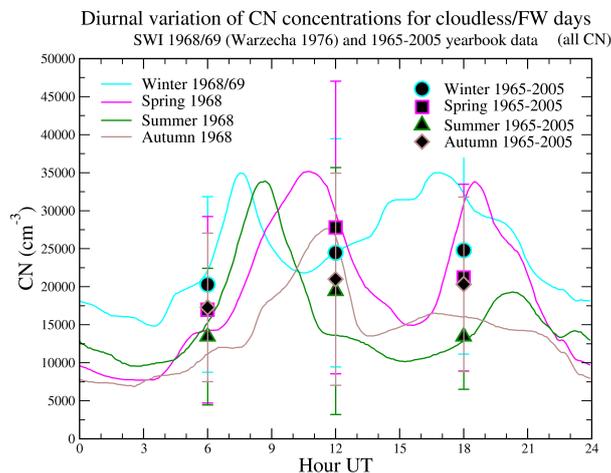

Figure 6. Diurnal variation of CN concentration values for cloudless days in spring 1968 – winter 1968/1969 and mean CN concentrations measured for 6, 12, 18 UT in 1965–2005.

4.2 Seasonal and annual variation

Analogously to Fig. 4 in Fig. 7 we show the seasonal differences in the distribution of FW PG at different CN concentrations. Their main statistical parameters for seasonal distributions are given in the figures as well as in Table 2. Fig. 7 presents the seasonal histograms of the hourly averaged (at 6, 12, 18 UT) FW PG values for 1965–2005. Each histogram contains two types of distributions: red colour indicates the FW PG values measured simultaneously with CN concentrations, and green colour indicates a subset of the FW PG values for CN concentrations less than 10000 cm^{-3} . The main statistical measures for both of these distributions are displayed within each plot. Depending on the season we observe different PG distribution characteristics. For spring, summer and autumn most values ranged between 100-300 V/m with mean value of ~ 250 V/m in the spring and autumn and ~ 200 V/m in the summer. Winter values ranged between 200–400 V/m and the mean was ~ 350 V/m. The standard deviation is also the highest in the winter. The kurtosis values during spring and autumn are 4.7-4.8 while the summer kurtosis is the highest at 5.7 and the winter is the lowest at 3.2. The skewness of the winter distribution is the lowest of 0.6, and the skewness of all the other distributions is between 0.8-1.2 indicating more values concentrated around the mean value. Limiting the CN concentrations does not significantly change the distributions of corresponding PG values.

Another way to look at the relationship between aerosol or condensation nuclei concentration is presented in the Fig. 8. Intensity of colour indicates the number (counts) of data points at certain range of PG and CN. Here the PG values are plotted against CN concentrations by season. In the summer there seems to be little influence of CN concentration on PG as the similar range of PG values is observed at wide range of CN concentrations. Some kind of dependency is visible in the winter, and spring and autumn are intermediate in this manner with some high PG values at high CN concentrations.

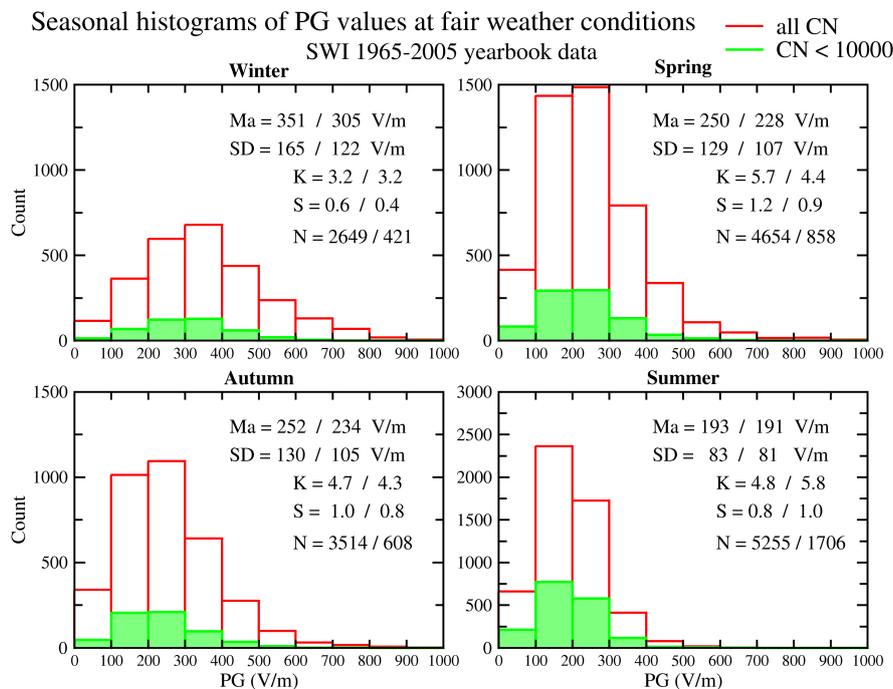

Figure 7. Seasonal histograms of the hourly averaged (6, 12, 18 UT) PG values measured during fair-weather conditions in January 1965 – December 2005: red colour–PG values measured simultaneously with all CN concentration values (6, 12, 18 UT), green colour–PG values measured simultaneously with CN concentrations below 10000 cm^{-3} . Note that the Y-axis ranges for summer (0-3000 counts) is twice compared with the other seasons (0-1500 counts).

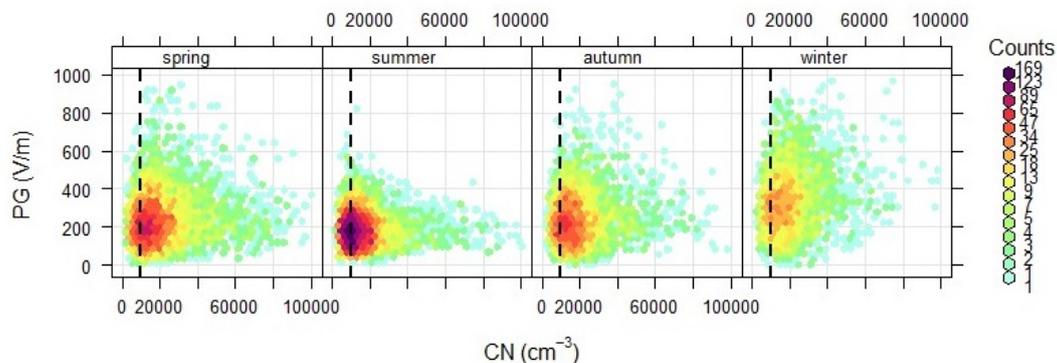

Figure 8. Seasonal dependence of hourly averaged values of fair-weather PG and CN concentration values in January 1965 – December 2005. Horizontal dashed line indicates the limit of CN concentration at 10000 cm^{-3} .

170 5 Diurnal, seasonal and annual variation at different level of CN concentration

Atmospheric potential gradient strictly depends on local conductivity of the air. The process of attaching of highly electrically ions to the aerosols causes reduction their mobility and, consequently, a decrease of local conductivity and an increase of the PG values (e.g., Israël, 1973a; Bennett and Harrison, 2008; Matthews et al., 2019; Wright et al., 2020). In this section we analyse if limiting CN concentrations to the lowest ranges in the CN distribution affects the PG values. We consider CN concentrations below 10000 cm^{-3} (green histograms in Fig. 4) and decrease the concentration limit by 2000 cm^{-3} (10000 cm^{-3} , 8000 cm^{-3} , 6000 cm^{-3}) to investigate the diurnal, seasonal and annual variations of PG at the lowest CN concentrations. In earlier sections we showed that limiting the CN concentration to 10000 cm^{-3} did not change significantly the PG distributions, here we investigate if any possible extreme limits affect this behaviour. Right part of Table 1 presents the counts and percentages of the whole PG population of values within each CN concentration limit. In Fig. 9, in the upper panel we show the histograms of CN concentrations and in next panels are shown the histograms of PG values at the three selected limits of CN concentration. There are 3736 values below 10000 cm^{-3} , 2086 values below 8000 cm^{-3} and 939 values below 6000 cm^{-3} , which is about 23 %, 13 %, 6 % of all CN concentrations, respectively. Below 4000 cm^{-3} there was only 123 values (0.8 %) and therefore this subset was not taken into account. These values represent the whole span of the studied time period, as shown in the small panel in the top panel of Fig. 9. They also represent all seasons as shown in Table 6, even though there is proportionally more counts in the warmer season because of better FW conditions. In the lower panels of Fig. 9 the histograms of corresponding PG values are shown. We note a slightly decreasing tendency in the mean value of the population especially at CN concentrations below 6000 cm^{-3} approximately 210 V/m and lower kurtosis and skewness compared with the distributions below 10000 cm^{-3} and 8000 cm^{-3} .

Seasonal means are shown in Table 3 and Fig. 10 for each hour term (6, 12, 18 UT) and the mean average over the terms, together with the standard error of the mean. Here we also notice a decrease in the mean values of PG for each term at lower CN concentrations particularly at 6000 cm^{-3} limit (i.e., comparing PG values between CN-all and CN below 6000 cm^{-3}). This is present in the winter (73 ± 15 V/m or ~ 13 % for total mean value), spring (30 ± 8 V/m or ~ 12 %) and autumn (29 ± 9 V/m or ~ 12 %) and the decrease are larger for 6 UT (e.g., 30 ± 12 V/m or 12 % in the spring) and 18 UT (e.g., 57 ± 29 V/m or 15 % in the winter, 36 ± 23 V/m or 14 % in the spring). However, in the summer there is practically no effect of CN and no clear tendency of decrease or increase (the largest decrease of several V/m only).

Finally, in Fig. 11 and Table 4 the annual variation of FW PG is presented, calculated as monthly averages. Additionally in Table B3 in the Appendix B the number of FW PG values calculated as monthly values for all and limited CN concentration is presented. PG variations calculated at 6, 12, 18 UT are plotted separately from the average curve. The maximum of the PG is in February which is also the maximum at 12, 18 UT. The minimum of PG is in June which is also the month of the minimum at 6, 12 and 18 UT. The lowest PG amplitude of the differences between the maximum and the minimum are in the 6 UT curve: 91 ± 12 V/m (wide maximum Dec-Mar, minimum in June) and much higher PG differences are at 12 and 18 UT: 213 ± 12 V/m (Feb-Jun) and 217 ± 13 V/m (Feb-Jun/Jul), respectively, 174 ± 7 V/m (Feb-Jun) in the average curve.

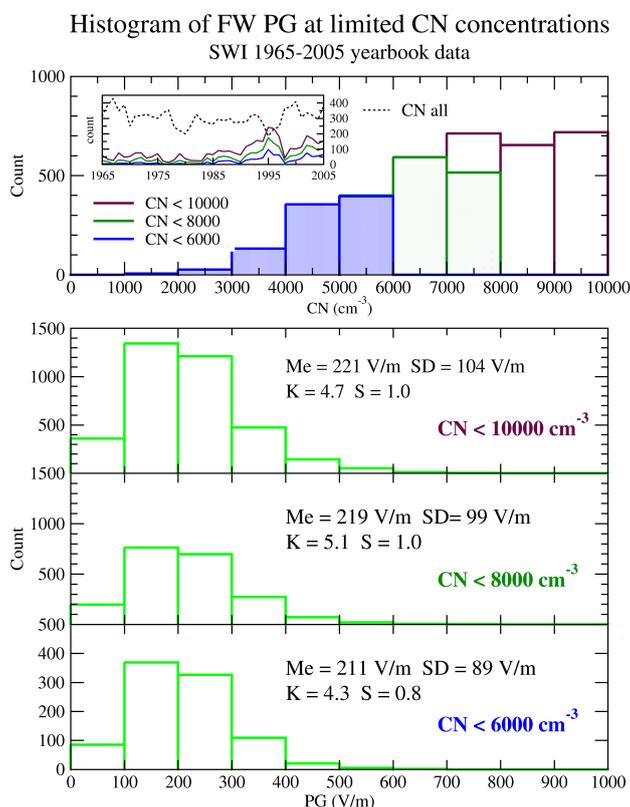

Figure 9. Histograms of the limited CN concentration values measured during fair-weather conditions divided into CN range: below 10000 cm^{-3} (purple), 8000 cm^{-3} (green), and 6000 cm^{-3} (blue), Bottom panels: histograms of hourly averaged PG values measured at limited CN concentration.

In the PG variations represented by the curves calculated with limitations of CN concentration there is a significant reduction of PG from October to March (11 %–26 %) and the biggest differences are seen in February at each term 6, 12, 18 UT and on average. In February the PG decreases by $95 \pm 25 \text{ V/m}$ or 26 %. In January and November the change is about 20 % ($75 \pm 24 \text{ V/m}$ and $58 \pm 20 \text{ V/m}$, respectively) and in December about 13 % ($45 \pm 28 \text{ V/m}$). From April to September there is a lack of or little influence of low CN concentration, and the PG differences are mostly of several V/m, which is of the order of the standard deviation of the mean error, except for April and September where these differences can be larger than 10 V/m. In September at 18 UT we note a larger decrease of PG of $44 \pm 29 \text{ V/m}$ (18 %). In addition, as we already have seen in the seasonal plots in Fig. 10 at 12 UT there is even an inverse relationship between the PG and CN. For example in July at 12, 18 UT and in August at 18 UT, although these differences are within the statistical error. In terms of the change of the amplitude of maximum–minimum differences at 6 UT there is a small change with decreasing CN concentration reaching $77 \pm 41 \text{ V/m}$ (Dec–Jun) at 6000 cm^{-3} CN limit. At 12 UT it is $165 \pm 35 \text{ V/m}$ (Jan–Jul) at 6000 cm^{-3} CN limit while at 10000 and 8000 cm^{-3} CN limit it is practically the same as with no limits ($\sim 213 \pm 12 \text{ V/m}$, Jan/Feb–Jun–Jul). At 18 UT at all CN limits the amplitude is ~ 160

Table 3. Mean values of PG measured for fair-weather conditions by season for all and limited CN concentration values together with the one standard error of the mean corresponding to 6, 12, 18 UT and on average.

Hour	Winter				Spring

215 V/m compared with 217 ± 13 V/m with no limits. There seems to be slight shift between the maximum or minimum month which is January or February for the maximum, and June and July for the minimum. In general, there are significantly lower differences between winter and summer in the annual variation of the FW PG at the lowest CN concentration limit considered, however, the maximum still stays in the winter (Dec–Jan–Feb).

6 PG and conductivity model with variable aerosol content

220 In this section we model a hypothetical change in the PG when we limit the number concentration of CN. The relationship between atmospheric electric potential gradient and aerosol concentration is complex. These two most often measured variables are related through the electrical conductivity of the air. The conductivity, σ , is influenced by the loss of small atmospheric ions due to attachment to aerosol particles, and decreases when the attachment intensifies.

225 In fair weather the rate of the loss of ions is mainly due to the attachment to aerosol particles. The process of attachment is dependent both on the number concentration and the spectrum of the size of aerosol particles, and is usually expressed by the ion-aerosol loss term, in general being a sum of contributions over different aerosol types and sizes (e.g., Israël, 1973a; Tinsley and Zhou, 2006). The term can be replaced by the effective coefficient β and the total aerosol concentration N , i.e. βN as in Eq. 1. The other parameters in Eq. 1 are: $q = 1 \text{ cm}^3 \text{ s}^{-1}$ – ion production rate, $\alpha = 1.3 \times 10^{-7} \text{ cm}^{-3}$ – the ion recombination coefficient, $\mu = 1.5 \text{ cm}^2 \text{ V s}^{-1}$ – the ion mobility and $e = 1.6 \times 10^{-19} \text{ C}$ – the elementary electric charge. We assume that the
 230 mobility and concentration of positive and negative ions are equal.

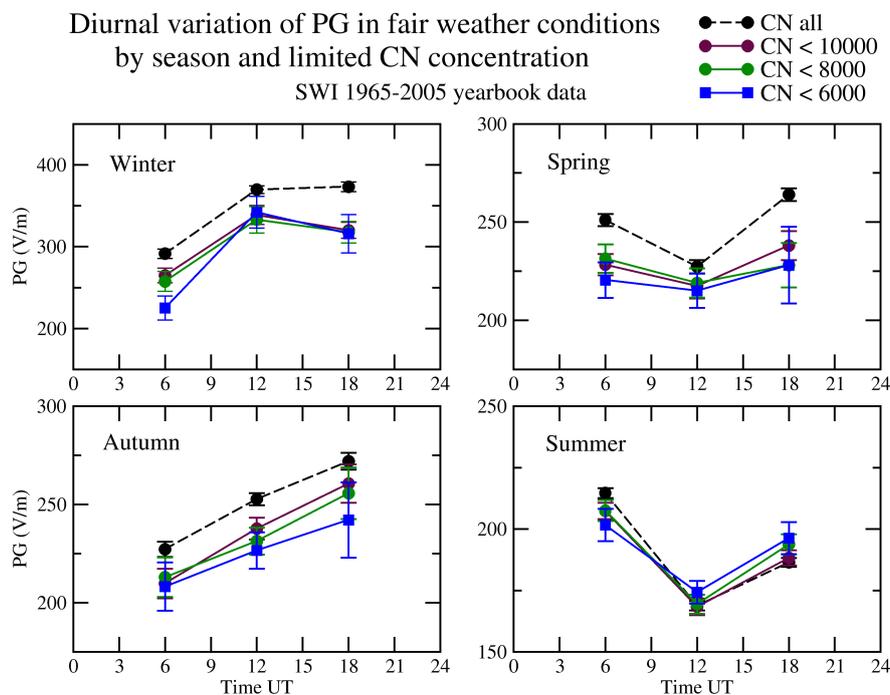

Figure 10. Diurnal variation of PG values measured during fair-weather conditions at 6, 12, 18 UT. divided into seasons, for the period January 1965 – December 2005 for all CN concentration values (black), and CN concentration values below: 10000 cm⁻³ (brown), 8000 cm⁻³ (green), 6000 cm⁻³ (blue). Error bars indicate one standard error of the mean.

$$\sigma = \frac{4e\mu q}{\beta N + \sqrt{(\beta N)^2 + 4\alpha q}} \quad (1)$$

In case where the conduction current, $j_C = \sigma PG$, is preserved, a decrease or increase in the electrical conductivity should result in proportional increase or, respectively, decrease in the potential gradient:

$$\frac{\sigma_2}{\sigma_1} = \frac{PG_1}{PG_2} = s \quad (2)$$

where indices 1 and 2 refer to value before and after the change, respectively.

According to Kubicki et al. (2016), rural continental aerosols of natural origin occurs in Świdler, but there is also a lot of pollution from suburban traffic and domestic heating (Majewski and Przewoźniczuk, 2009; Pietruczuk and Jarosławski, 2013).

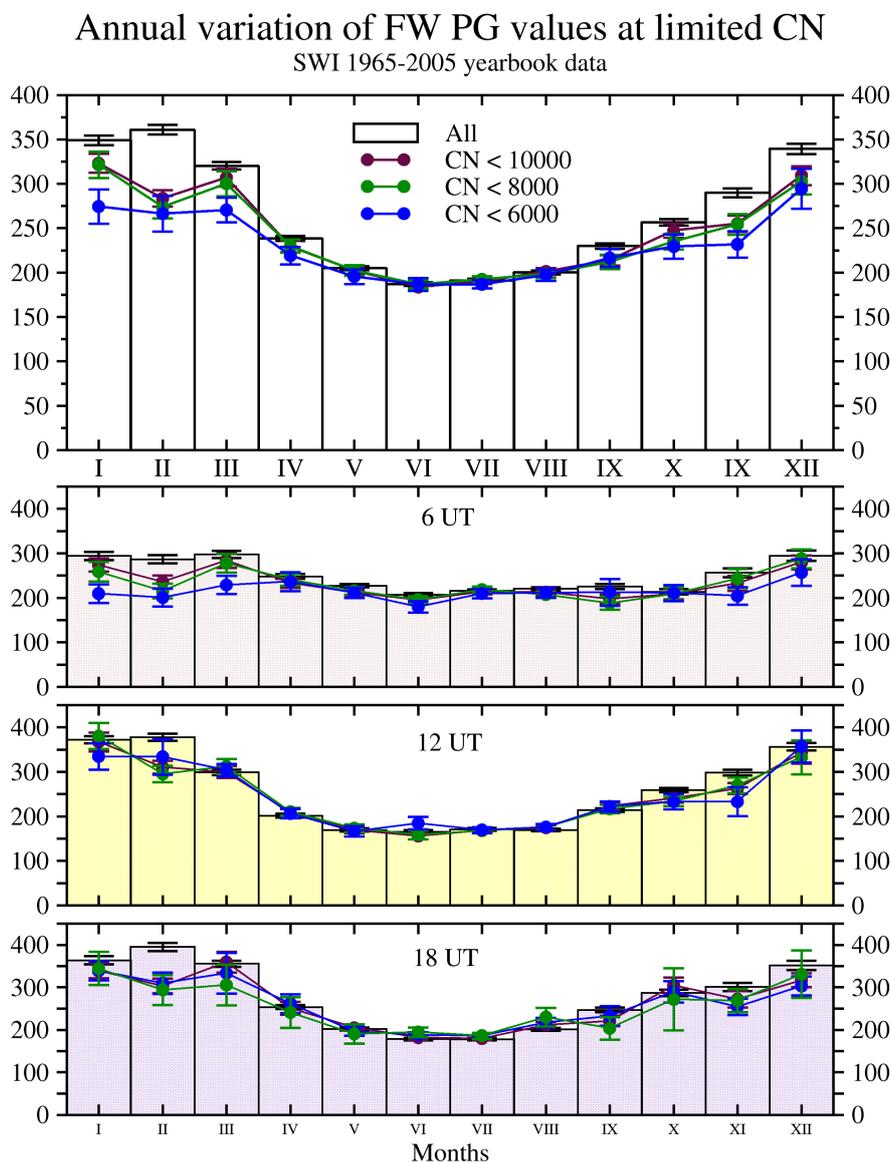

Figure 11. Annual variation of PG values measured during fair-weather conditions for all and limited CN concentration values for all hours (upper chart) and separately for each hour (6, 12, 18 UT). Error bars indicate one standard error of the mean.

Aerosol size observations show that polluted aerosol also occurs there and consists of large concentrations of fine particles dominated by the nuclei mode of the mean diameter 20–30 nm and the accumulated mode of the mean diameter 100–120 nm. Let us consider a mix of continental aerosol types the Świder aerosol may be composed of, and calculate the conductivities at variable aerosol composition and concentrations. In the first place we want to focus on winter conditions when the decrease of

245

the potential gradient at lower CN concentrations, expected to be due to decreasing effect of pollution on the air conductivity, is the biggest as obtained in Sec. 4. Next we estimate the effect during the summer.

According to Hess et al. (1998) a land aerosol may consist of 3-4 main aerosol types: continental clean, continental average, continental polluted, and urban. These aerosol types consist of three basic aerosol components: water insoluble (*WatInsol*), water soluble (*WatSol*) and soot (*Soot*), the two latest contributing almost 99 % of the total concentration and contained in the range of CN particle size. Their individual β coefficients are: $\beta_{WatInsol} = 2.80 \times 10^{-5} \text{ cm}^3/\text{s}$, $\beta_{WatSol} = 1.18 \times 10^{-6} \text{ cm}^3/\text{s}$, and $\beta_{Soot} = 5.56 \times 10^{-7} \text{ cm}^3/\text{s}$, respectively, obtained from calculations based on the equations used in Tinsley and Zhou (2006). In this model the effect of relative humidity on the conductivity is not included.

$$\beta N = \beta_{WatInsol} N_{WatInsol} + \beta_{WatSol} N_{WatSol} + \beta_{Soot} N_{Soot} \quad (3)$$

255

where $N_{WatInsol}$, N_{WatSol} , and N_{Soot} are number concentrations of the three aerosol components.

As a winter representative composition we choose a combination of the soot concentration up to 24000 cm^{-3} and the water soluble aerosol concentration up to 6000 cm^{-3} at different percentage ratio of water soluble – soot concentrations, and constant concentration of water insoluble aerosol of $N_{WatInsol} = 500 \text{ cm}^{-3}$. By increasing the concentration of water soluble aerosol we obtain mixes of aerosol of CN concentrations ranged from the seasonal average mean value (Fig. 4, Table 2) and the lowest considered limit of 6000 cm^{-3} . This results also in variable ion conductivities. Table 5 presents the changes of the winter CN concentration, the ion-aerosol loss term, ion concentration and ion conductivity at different proportions of water soluble and soot aerosol components. The different proportions give the range of CN concentration between 6500 cm^{-3} (~100 % of water soluble aerosol) and 24500 cm^{-3} (~100 % of soot). The air conductivity calculated from Eq. 1 is then between $2.28 \times 10^{-15} \text{ S/m}$ and $1.76 \times 10^{-15} \text{ S/m}$.

As a summer representative composition we choose a combination of soot concentration up to 14000 cm^{-3} and water soluble aerosol concentration up to 6000 cm^{-3} at the different percentage ratio, in addition to the constant concentration of water insoluble aerosol at $N = 500 \text{ cm}^{-3}$. The combinations give the range of CN concentrations between 6500 cm^{-3} (~100 % of water soluble aerosol) and 14500 cm^{-3} (~100 % of soot), and the ion-loss term βN is calculated according to Eq. 3. The air conductivity is then between $2.28 \times 10^{-15} \text{ S/m}$ and $2.15 \times 10^{-15} \text{ S/m}$, as shown in Table 6.

The winter composition leading to the CN concentration of about 6000 cm^{-3} result in the ion conductivity $2.28 \times 10^{-15} \text{ S/m}$, which is 1.3 the initial value of $1.76 \times 10^{-15} \text{ S/m}$ at 24500 cm^{-3} CN concentration, and the intermediate mixes give a monotonic increase of conductivity by 30 %. The summer case leading to the same low concentration of CN and the conductivity of $2.28 \times 10^{-15} \text{ S/m}$, which is 1.06 the initial conductivity of $2.18 \times 10^{-15} \text{ S/m}$ at 15500 cm^{-3} . The intermediate mixes give an increase of conductivity by up to 6 % only. This should result in 30 % lower value of the PG according to Eq. 2 in the winter and 6 % decrease of the PG in the summer. Further, according to the model and Eq. 2, situations with low CN concentrations should result in at most 30 % decrease of the PG in the winter and up to 6 % decrease of the PG in the summer.

7 Discussion

280 At many land atmospheric electricity stations, including Świder, the increase of the potential gradient during local wintertime or rush hours, which is usually related to increase of emission from intensive domestic heating and transport, is considered to be due to a decrease in the electrical conductivity (Harrison, 2006; Kubicki et al., 2016; Tacza et al., 2021). Having at disposal all digitised PG hourly values we calculated the diurnal variation of PG from all available fair weather hours. As in the previous results of such analysis at Świder (e.g., Warzecha, 1991; Kubicki et al., 2007), made on the basis of 24-hour fair-
285 weather days 1965-2000, or fair weather hours during days with 12 hours of FW conditions over the time period 2004–2011 (Michnowski et al., 2021) the PG diurnal variation shown in Fig. 5 confirmed the different behaviour according to season. The double oscillation is evident during spring, summer and autumn (in the summer with peaks at 7 and 20 UT), and in winter a single oscillation (a minimum at ~3UT and a peak at 19 UT). Similar PG diurnal curves were found in Reading for summer and winter (Nicoll et al., 2019). One hypothesis for the two PG peaks found in summer at urban sites could be due
290 to pollution of vehicular traffic during rush hours. Majewski and Przewoźniczuk (2009) performed Particulate Matter ($10\mu\text{m}$) measurements for eleven stations in Warsaw. They found clear two peaks (7 and 20 UT) in warm weather (April to September) and less pronounced peaks in cold weather (October to March). As mentioned earlier, Świder is located in a suburban site so vehicular transportation is not expected affect too much in the PG diurnal variation. Then, the hypothesis for the difference in the PG diurnal variation in summer and winter is a combination of “sunrise effect”, generally thought to be related to mixing
295 of the near-surface electrode layer (which is an accumulation of positive charge next to the negatively charged Earth’s surface). The first peak (at ~7 UT) could be associated both with the dynamic changes in the planetary boundary layer and generation of the secondary aerosol.(Kubicki et al., 2007). Then, as the temperature is continuously increasing, the convection intensify producing mixing processes in the PBL causing transport of aerosol to higher altitudes and therefore, the PG decreases. As the temperature decrease after 16 UT the PG return to normal values. In winter, the reduced variability in PBL height (due
300 to diminished convection) therefore leads to more quiescent meteorological conditions which results in a more stable diurnal variation in PG, and the disappearance of the morning maximum peak (see also Nicoll et al., 2019).

The annual cycle of emissions with maxima in the winter and minima in the summer affecting the land PG measurements (Adlerman and Williams, 1996; Nicoll et al., 2019; Shatalina et al., 2019) are considerable at Świder, as confirmed in the analysis in Sec. 3 (Figs. 5, 6, 8). Similar behavior in the PG seasonal variation was found in Kew and Reading, in the UK,
305 and Nagycenk, in Hungary (März et al., 1997; Harrison and Aplin, 2002; Nicoll et al., 2019). Harrison and Aplin (2002) associated the PG higher values during winter, at Kew, to the influence of smoke pollution. März et al. (1997) suggested that the PG seasonal variation at Nagycenk is likely associated to the condensation nuclei variation. Nicoll et al. (2019) suggested that the PG higher values during winter at Reading is due to more use of domestic heating, and it is very likely that at Świder the PG values are higher during winter due to domestic heating producing soot. This is also in agreement with the simple
310 conductivity model in this work. Measurements of $\text{PM}_{2.5}$ in Krakow (south of Poland) found higher $\text{PM}_{2.5}$ concentrations during winter month compared with summer months for the period from 1 February 2020 to 27 March 2021 (Ryś and Samek,

2022). The time intervals of this study and the PG measurement at Świder are different (in fact both site locations are very far away), however, a similar behavior in PM is very likely at Świder.

315 The aerosol concentration changes also annually due to variation in convection processes in the planetary boundary layer (PBL), and the PBL height, more influential during warm season and especially in the local summertime. At Świder, as discussed in Sec. 2.1, the summer CN concentrations differ much more from the rest of the year (Fig. 4) being minimal through all the year. As opposed to winter the change in the summer concentrations does not seem to be so significant on average (Fig. 9). The effect of reduced aerosol concentration to its lowest levels did not change the average PG amplitude in the summer, while in the other seasons this effect was observed particularly in the winter (Sec. 4).

320 According to the conductivity model for varying ground-level CN concentrations characteristic for Świder, described in Sec. 5, there could be $\sim 30\%$ decrease of the PG as a result to changes of the ion conductivity in the winter conditions with enhanced content of soot aerosol, and only a few percent decrease in the summer. The maximum decrease of the PG that we observe at the CN concentration of 6000 cm^{-3} in the winter is about 1.15 times and in the summer 1.03 times (see Table 3), which fairly agrees with the experimental model, itself not devoid of simplifications such as effects of humidity, constant ion
325 production. The differences between the model and observations should also arise from other factors affecting the PG such as, e.g., space charges, formation of secondary aerosol, or the conditions when the vertical particle current has other components than the conduction current, e.g. during convection etc. (e.g., Markson, 1975; Hoppel et al., 1986; Anisimov et al., 2017).

The changes of PG due to changes in the conductivity obscure the real changes of the PG resulting from the activity of the GEC, and the annual maximum of PG occurs usually during local winter. In this work we wanted to investigate in what way
330 taking into account fair weather PG values at low CN concentrations affects the PG annual maximum. In general, our results show that even though the PG decreases at low CN concentrations, ~ 10 times more in the winter than in the summer (less than $10000, 8000, 6000\text{ cm}^{-3}$) the maximum of PG remains in the winter. More recent analysis of the annual variation of PG in several places of different character of climate and pollution conditions show the PG maximum occurs in March and April.

8 Summary

335 The findings of this work could be summarised as follows:

- We calculated diurnal, seasonal and annual variations of fair-weather potential gradient based on 1965–2005 digitized time series of data from Świder observatory yearbooks, and we provided details of the statistics for the PG and the condensation nuclei CN number concentrations, measured during this period at three specific hours of measurement (6, 12 and 18 UT). The general average mean of PG is 230 V/m, and the average PG at the CN concentration observation
340 terms is 248 V/m while the CN average mean is about 19000 cm^{-3} . The PG and CN distributions are both leptokurtic (i.e., narrow) and right-skewed. A subset of PG values for CN concentration below 10000 cm^{-3} (which correspond to 20 % of the whole CN-PG pair data) was selected for further analysis of the effect of aerosol concentration on the PG variation. In particular, we aimed to investigate the PG annual variation in connection with the GEC variability. The PG

- 345 average mean for reduced levels of CN concentrations is 221 V/m, and the CN average mean in this subset is 7290 cm^{-3} .
- Summer and winter months have a clear signature in the PG diurnal variation for all CN concentrations, likely associated with mixing processes in the planetary boundary layer. For the subset with CN below 10000 cm^{-3} , we found that PG values do not show any significant variation in summer. On the other hand, for winter we found a big PG difference (11 %). Furthermore, this PG difference is about 20% when we considered CN below 6000 cm^{-3} .
 - 350 – Local winter months have higher PG values compared with local summer months, a common feature of continental atmospheric electricity stations. Furthermore, this PG seasonal variation is maintained even at lower CN concentrations (e.g., 10000, 8000, 6000 cm^{-3}). We found that there is a reduction in the PG values by 11-26 % with the biggest difference in February. In summer months, this difference is negligible. From this, we can conclude that aerosol at these concentrations has more effect in the PG during winter compared with summer.
 - 355 – A simplified modelling of electrical conductivity affecting the PG is created. The ion loss in this model is due to attachment mainly to water soluble aerosol particles and soot particles, the main components of continental aerosol. At different percentage ratios of these two components leading to low total concentration of CN (down to 6500 cm^{-3}) we obtain changes in the conductivity and the PG in fair agreement with observations up to 30 % in the winter, and 6 % in the summer.
 - 360 – Despite our efforts to minimise the aerosol effect on the PG (through CN concentration measurements), the character of the PG seasonal and annual variation does not radically change, with the maximum remaining in the winter and the minimum in the summer (Northern Hemisphere winter and summer).
